Under natural circumstances, annual recruitment and differential mortality determine population growth. Annual recruitment provides the initial age class every year and differential mortality acts on the population as a whole. In a seeded population of abalone, there is no natural annual recruitment. The seeding number provides the recruits, while the natural process of differential mortality then acts upon the seed. The seeding process is traumatic and initial seeding-induced mortality can be very high (Shepherd et al. 2000, Schiel 1993, de Waal & Cook 2001). Handling and transport, and behavior after release, all play a role in the initial survival of seeded animals. These factors can be addressed, to a certain extent, by improving handling techniques and site selection, and increasing size at release. However, the environmental factors that have a more long-term effect on the differential mortality rates in a population, generally lie outside the realistic scope of human influence. These are also the factors about which the least data exist. When determining total mortality, the impact of initial mortality and differential mortality can be separated from each other to an extent. This can be done by changing the length of the period between seeding and sampling. The shorter the period between release of seed and sampling, the more dominant the effects of seeding induced mortality. The longer the period between seeding and sampling, the stronger the effects of long term differential mortality rates. A period of 30 days has been shown to be long enough for a seeded population of *H. midae* to stabilize after initial seeding-induced mortality. A seeded population that has been in the water for that length of time can be safely assumed to be driven by the same natural environmental factors that affect a natural population in the same habitat.

A model was developed using theoretical differential mortality regimes (Fig. 1a), and experimental initial survival figures for abalone of different sizes (For the purpose of the model, post-seeding survival rates can be interpreted as different initial seeding population sizes). Post seeding survival figures were used as initial population figures in the cost-benefit analysis in this article, and random number generators were used in the sensitivity analysis to initiate populations.

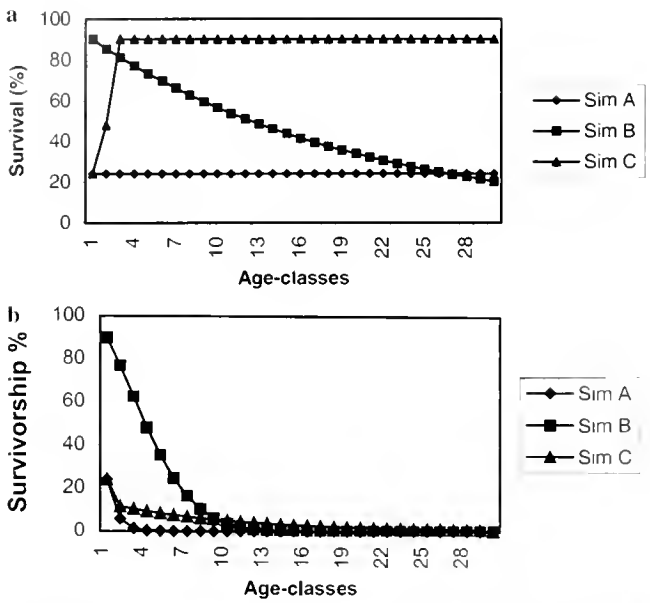

Figure 1. (a) Differential mortality rate regimes used in Simulations A, B, and C. Simulation C is the one selected as being most realistic with survival increasing per age class to a maximum of 90%. (b) Survivorship curves generated by Simulations A, B, and C. These curves show the cumulative effect of differential mortality rates. Although the lines converge over time, the differential mortality rates from Figure 1a were chosen to be completely different. This shows the importance of knowing the actual mortality rates.

METHODS

Description of the Model

To determine population frequency per age class (n) at a specific time period (t), the population frequency in the previous time period (n at t − 1), was multiplied by the age-specific percentage survival figure from the year (t) in the formula:

$$n_t = (n_{t-1}) \times (\%\ \text{survival per age class})_t$$

To determine the percentage survival per age class at a specific time period (t), the percentage survival per age class for the previous time period (t − 1), was multiplied by a factor equal to, greater than or smaller than 1. If the factor is equal to one the percentage survival per age class remains the same for the following year. If the factor is greater than one, survival per age class increases per age class. In other words, the older an animal becomes the less chance it has of dying. If the factor is less than one, survival per age class decreases and the percentage chance of dying increases with age.

Age class frequencies were calculated as an average at the end of a cycle (one run), which for simulation purposes could be up to 30 y, the maximum life span for *H. midae* (Tarr 1995). Age class periods were equal in length of time to the first time period. All simulations in this case were done in time periods of 1 y.

The following are assumptions made to develop the model.

1. Differential mortality rates were developed using the assumption that percentage mortality per age-class either increased or decreased by a constant factor in consecutive age classes (Fig. 1a).
2. Differential mortality rates included all limiting factors on survival, density dependence, senescence, carrying capacities etc.
3. Maximum survivorship of any age class could be 90% of the previous age class. (Average annual mortality is taken to be approximately 11% for all size classes of natural abalone stocks by the Marine and Coastal Management Institute of South Africa (pers. com. C. Moloney).
4. There was no natural recruitment taking place in the seeded population.

Investigating the Range of Potential Differential Mortality Regimes

While a range of differential mortality rates may exist for any species in a range of habitats, it was necessary to restrict the investigation to only three experimental options. In the following simulations, an initial survival figure of 24% was used.

Simulation A

A basic approach to modeling a differential mortality regime is to assume a constant mortality rate per age class throughout the entire population, regardless of age. This is a simplistic approach and there are no indications that *H. midae* does behave in this way (Fig. 1a).

Simulation B

In this case, it was assumed that mortality increased per age class by 5% per year from a maximum survival rate of 90%. However unrealistic, this allowed a broader investigation into the possible survival options and behavior of the model (Fig. 1a).

Simulation C

In this case it was assumed that mortality decreased per age class, survival per age class doubled to a maximum of 90% (Fig. 1a). The shape of this survival curve seems to be the most realistic option, although the exact age or size specific differential mortality rates and the gradient of the curve are not known. (Tegner 2000, de Waal & Cook 2001, Shepherd et al. 2000, Schiel 1993).

Figure 1b shows survivorship per age class generated by the percentage survival per age class curves from Figure 1a and the initial population number of 240,000 (based on a 24% post seeding survival figure). Figure 1b shows the cumulative survival percentage or the probability of an animal reaching a certain age. This was the figure that indicates the yield per recruit of a seeding operation in terms of age class frequency distributions.

Sensitivity Analysis of the Model with Regards to Survival Regime and Initial Survival

It was necessary to test the behavior of the model in relation to the two driving variables, seeding induced mortality and differential mortality. To do this, the model was run with stochastic recruitment generated at the beginning of each year. Two hundred runs were done for each scenario analysis. A random number generator between 1000 and 100 million was used to simulate recruitment at the beginning of every year.

Four general scenarios were developed to test the sensitivity of the model to the two variables (Fig 2). In Group 1, differential mortality rates were manipulated over time while initial survival figures, or initial population sizes, were kept constant. In Group 2 differential mortality rates were kept constant while initial population sizes were manipulated over time.

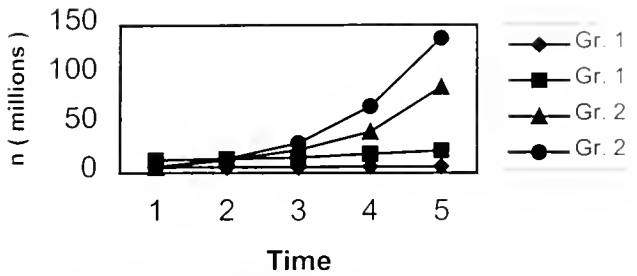

Figure 2. Sensitivity analysis results in which either initial population numbers were manipulated while differential mortality rates per age class were kept constant over time, Group 2. Alternatively, differential mortality rates were manipulated while initial population size was kept constant, Group 1. The period of time is conceptual and is only used to show the difference in total population numbers as a result of manipulating the two driving variables.

Cost-Benefit Analysis

A simple cost-benefit analysis was developed using experimental initial survival figures for both 14-mm and 26-mm seed sizes, a range of differential mortality regimes, and the present market price for abalone. A purchase price of R 1 per animal for 14-mm animals and R 4 per animal for 26-mm animals, and a selling price of R210 per kg for 300 g abalone, were assumed. The exchange rate used was R 6 (SA) to $1 (US). Prices were quoted by Port Nolloth Sea Farms.

A series of differential mortality rates were used in which survival per age class ranged from being constant to increasing by 60% per age class as the population ages. Initial population figures were based on experimental data (de Waal & Cook 2001), 24% for animals with an average size of 14/mm, and 56% for animals of average size 26/mm. One initial seeding batch was allowed to run the course of the model to a market size of 300 g. Using an average growth rate of 1.5 mm per month, and a mass-length curve measured from animals that have been at sea at Kleinzee for 13 mo, this size would have been reached after approximately 6.5 y (unpublished data).

RESULTS

Sensitivity Analysis

Both driving variables, seeding induced mortality and differential mortality, had an influence on the model output in terms of the rate of population decrease. Over the same time period, in those simulations in which initial population size was manipulated, Group 2 (Fig. 2), the proportional impact was far greater than in those simulations in which differential mortality rates were manipulated, Group 1 (Fig. 2). While model output was generated by a combination of the effects of both variables, it is clear that initial survival after seeding-induced mortality had stabilized, played the dominant role.

Cost-Benefit Analysis

With an average growth rate in the range of 1.5 mm per mo measured in Port Nolloth for farm-reared juveniles, it would take approximately 9.5 mo for animals to reach 14/mm, and a further 7.5 mo to reach 26 mm, a total of 17 mo. The animals seeded at size 14 mm would reach harvesting size after 6 y at sea. The animals seeded at 26 mm reached that size after 5 y. On average however, harvesting for both seeding scenarios could take place in the seventh year after spawning. Growth rates are variable and this must be kept in mind when interpreting analyses. For example, the estimated time to legal size for experimental animals seeded at Port Nolloth was estimated to be anywhere between 3.5 y and 6 y (Sweijd et al. 1998).

DISCUSSION

The model was designed to investigate the dynamics of a single population of abalone, based on contemporary knowledge of the dynamics of abalone in general. The ultimate goal would be to generate experimental data to the point where modeling can be based on accurate differential mortality and initial survival figures. At this stage, this was not possible. However, a choice based on scientific facts could be made between realistic and unrealistic options. Indications from this project, and from contemporary literature, are that differential mortality decreases with age, i.e. survival increases until senescence sets in. Davis (1995) estimated survival of juveniles in artificial habitats to be 32% after 1 y and 24% after 2 y. In other words, in the second year survival had increased to 75% compared to 32% in the first y. Seeding-induced mortality would account for a large percentage of the first y mortality, and differential mortality would account for the decrease in mortality of the seeded population in the second year (Shepherd et al. 2000). Seeding-induced mortality is clearly the most important factor to consider when seeding.

The percentage survival and the survivorship curves, in Figures 1a and 1b, showed very clearly that it is quite possible for theoretical curves to converge at some point. If only one point value is known, very little could be determined about the dynamics of the model. To model production accurately, it would be necessary to have a good idea of the differential mortality regime acting in that specific habitat. The goal of objective research should, in this case, be to determine the most realistic mortality regimes in any given situation. Models used with appropriate experimental data will allow analysis of the feasibility of projects before any serious financial input is made and should be used and developed as more biological data become available (Munro & Bell 1997, Wilson et al. 1998, Heppel & Crowder 1998, Hilborn 1998). It is absolutely essential to understand the concept of differential mortality and survival before any predictions can be made about the success of seeding programs.

The model showed that, with the quoted purchase price of seed, it is not economically viable to seed juvenile abalone of either size if the survival per age class does not increase by at least 10% per age class. If the survival per age class increases by more than 40% per age class, it would be viable to seed even the smaller animals. The model showed very clearly that there was an exponential increase in potential yield for larger seed animals compared to smaller seed animals (Table 1). This is a reflection of what happens under natural conditions (Shepherd at al. 2000, Schiel 1993, Tegner 2000). Experimental results by De Waal & Cook (2001) have shown an exponential increase in survival of juvenile abalone with an increase in seeding size. This could possibly be attributed to an increase in muscle and shell strength of the juvenile *H. midae*. Both behavior and the ability to adapt could also play an important role in this differential survival. According to the model, this difference in potential yield was caused by both the strong effect that initial survival has on the model output, and by the speed at which high initial survival causes the survival per age class value to reach a maximum of 90%. It is important to note that while experimental evidence suggests (unpublished data) that both

TABLE 1.

Cost-benefit results for abalone harvested after approximately 6.5 years at sea.

Survival Per Age Class	Seeding Size mm	Harvesting Mass kg	Buying R (mill)	Selling R (mill)	Profit R (mill)
Remains constant	14.00	13.76	1.00	0.00	−1.00

	26.00	99202.32	4.00	20.83	16.83

adults and juveniles may survive well in the same habitat, this may not always be the case. Seeding must be done in an area in which both initial mortality and long term mortality are as low as possible.

In any potential ranching and stock enhancement project, production costs that are too high do not allow continuation. This model has allowed an insight into the limitations set by natural processes before the production process has begun (Hilborn 1998, Moksness et al. 1998, Schiel 1993). Production costs could be much lower than the quoted purchase prices and better potential income could be obtained by producing low-cost abalone seed rather than purchasing it. A trade-off exists, not only between supply and demand in terms of the market price of abalone, but also between market price and the seeding strategy and site characteristics of the project concerned. In abalone ranching, production costs must be seen to include both the negative effect of initial seeding mortality and the negative effect of the potential differential mortality rates that exist. The importance that these two variables have on the potential economic viability of a ranching project, and the lack of experimental data concerning these variables, emphasizes the need for additional research in this field.

ACKNOWLEDGMENTS

This research was funded by both Port Nolloth Sea Farms and the South African Foundation of Research and Development (T.H.R.I.P.) fund. We thank both Professor John Field and Dr. Colleen Moloney for their advice on both the model and the manuscript.

TRANSMISSION OF THE RICKETTSIALES-LIKE PROKARYOTE "*CANDIDATUS XENOHALIOTIS CALIFORNIENSIS*" AND ITS ROLE IN WITHERING SYNDROME OF CALIFORNIA ABALONE, *HALIOTIS* SPP.

JAMES D. MOORE,[1]* THEA T. ROBBINS,[1] RONALD P. HEDRICK,[2] AND CAROLYN S. FRIEDMAN[1,2]

[1]*California Department of Fish and Game, UC Bodega Marine Laboratory, 2099 Westside Road, Bodega Bay CA 94923;* [2]*Department of Medicine and Epidemiology, UC Davis School of Veterinary Medicine, Davis, CA 95616*

ABSTRACT Withering syndrome (WS) is a chronic, wasting disease responsible for mass mortality in southern California populations of black abalone *Haliotis cracherodii* and responsible for significant losses of cultured red abalone *H. rufescens*. Ongoing studies in our laboratory indicate that a recently described gastrointestinal Rickettsiales-like prokaryote, "*Candidatus Xenohaliotis californiensis*" (RLP) is the etiologic agent of WS. Here we describe attempts to experimentally transmit the RLP and demonstrate its role in WS. In two preliminary experiments, RLP-infected black abalone postesophagus homogenate (PEH) was injected into the foot or orally administered to RLP-free black abalone. No RLPs were detected 8 wk after pedal injection. Low rates of transmission were observed 8 to 12 wk after oral inoculation, although an RLP-positive animal was also detected in a negative control group inoculated with filtered seawater. In a separate, 16-wk study, RLP infections were detected in red abalone that received effluent from a tank of infected red abalone while control animals that received direct-source seawater remained RLP-free. A fourth, long-term study delivered PEH or seawater to RLP-free red abalone with either bath exposure or intra-digestive gland injection. An additional treatment to test a potential viral etiology for WS consisted of intra-digestive gland injection with a 0.1–0.2 μm filtrate of PEH and subsequent treatment with antibiotics. Each treatment was administered six times over a 16-wk period. Cohabiting RLP-infected black abalone with RLP-free red abalone provided a positive control treatment. At wk 63 post-initiation, untreated, saline injected and PEH filtrate injected groups had low cumulative mortality (0–20%), while mortality in the PEH bath, PEH injection and cohabitation treatment groups was 70–90%. There were statistically significant relationships between experimental treatment, RLP burdens and signs of WS. Low-level RLP infections of uncertain origin were observed in one each of the duplicate tanks of the negative control and the PEH filtrate-injected animals. An absence of WS signs in recipients of the PEH filtrate provides strong evidence that the agent of WS is non-viral. Collectively these studies provide solid evidence that the RLP is the etiologic agent of WS.

KEY WORDS: *Haliotis rufescens, cracherodii*, Rickettsiales, withering syndrome, transmission, abalone

INTRODUCTION

The black abalone *Haliotis cracherodii* is one of several haliotid species found on the Channel Islands and mainland of southern and central California, USA. This species lives in the intertidal zone and is considered less desirable for human consumption than several subtidal species, but became an important component of the commercial fishery in the 1970s when stocks of subtidal species declined, presumably due to increasing recreational and commercial fishing pressures (Davis et al. 1992). Resource managers and abalone fishermen first noticed large numbers of dead and dying black abalone on the Channel Islands in the mid-1980s (Haaker et al. 1992). The term Withering Syndrome was coined to describe the affected abalone, characterized by lethargy and a greatly reduced pedal mass (Haaker et al. 1992). Southern California black abalone populations have essentially collapsed, with mortality greater than 90% in many areas (Haaker et al. 1992, Richards & Davis 1993). Stocks of subtidal red (*H. rufescens*) and pink (*H. corrugata*) abalone also declined during the 1980s (Davis et al. 1992) but the role of fishing pressure, climatic events and WS in those declines remains unclear.

Although the appearance and severity of WS outbreaks appeared to be enhanced by warm water temperatures (Steinbeck et al. 1992, Tissot 1995), the epizootiology of the disease indicated involvement of an infectious agent (Lafferty & Kuris 1993). WS spread throughout the Channel Islands followed by movement to the California coastline, where it advanced northward during the early 1990s (Lafferty & Kuris 1993, Alstatt et al. 1996). An initial investigation of nine black abalone with WS and five without signs of the disease reported the presence of several parasites and a gastrointestinal Rickettsiales-like prokaryote (RLP), although none occurred in all affected abalone while being absent in healthy-appearing abalone (VanBlaricom et al. 1993). The RLP formed large intracellular inclusions in gut epithelium, causing hypertrophy but little other cytopathology. RLPs are common endosymbionts in molluscs, often being unassociated with disease (Sparks 1985, Elston 1986). Gardner et al. (1995) examined black abalone from both where WS occurred and where it did not. They found that the RLP was present only in abalone from the WS-endemic site, and noted pathological changes in the digestive gland that could be due to the RLP. Subsequently, Friedman et al. (1997) examined starvation, temperature, the renal coccidian *Pseudoklossia haliotis* and the gastrointestinal RLP as causes of WS. While eliminating the coccidian, starvation and elevated temperature as being directly responsible for WS, complex relationships between the RLP and temperature warranted further investigation. Friedman et al. (this volume) transmitted WS and the RLP between black abalone. Groups of initially RLP-free black abalone that contracted the RLP by cohabitation with RLP-positive animals had a higher proportion of animals with signs of WS and higher proportion that died than did unexposed RLP-free control animals. However, the authors also observed a lack of significant correlations between WS signs and RLP infection intensity, further indicating a complex relationship in black abalone.

The RLP is not restricted in host species to the black abalone.

The RLP is present in most or all abalone aquaculture facilities in California, which raise red abalone to a market size of approximately 9 cm in land and cage-based operations throughout the state (McBride 1998). This is due to its increasing range in wild populations and the widespread distribution of infected seedstock prior to it being recognized as a potentially significant pathogen (C. S. Friedman, unpublished observations). During the 1997–1998 El Nino, red abalone aquaculturists in the southern and central portions of the state began observing sharply elevated frequencies of animals showing WS signs in association with elevated water temperatures. Recently, Moore et al. (2000) demonstrated that farmed red abalone with RLPs can show little or no signs of WS at lower temperatures (14.7°C), but elevation of temperature to 18.5 C caused elevated mortality, expression of WS signs and increased RLP burdens. With increasing evidence for its role in WS, Friedman et al. (2000) recently provided a description of the RLP, designated "*Candidatus Xenohaliotis californiensis*." The term "*Candidatus*" in the taxon indicates that the species was described largely on morphological and DNA sequence-based data and still requires the serological and biochemical analyses that would be performed if the species could be cultured *in vitro*.

The coinciding geographic boundaries and correlation between WS and the RLP do not alone demonstrate that this agent causes the disease. An alternative hypothesis suggests that the RLP proliferates in host animals debilitated by WS, itself caused by an unidentified, possibly viral agent. Our current studies, while limited by the difficulty of obtaining and maintaining RLP-free abalone, were designed to experimentally transmit the RLP and examine links between severity of RLP infection and expression of WS signs.

MATERIALS AND METHODS

The experimental designs of the four consecutive experiments conducted are shown in Figure 1. Experiments 1–3 were designed to investigate transmission of the RLP. Animals were therefore sacrificed at time periods of several weeks to several months, generally before expression of WS occurred. Experiment 4 was designed to allow sufficient time for development of WS and was terminated following extensive mortality in treatment groups 15 mo post-initiation.

Animals and Animal Husbandry

All experiments were conducted in the Pathogen Containment Facility at the Bodega Marine Laboratory, from which all effluent is treated with 10 mg/L chlorine for two hours and dechlorinated with sulfur dioxide before release. Lidded, 8-L tanks with outflows situated so that each tank held 5 L were used in Experiments 1–3. In Experiment 4, lidded 58-L tanks with standpipes situated to hold 50 L were used. All tanks received sand-filtered, aerated seawater and were supplied with kelp (*Macrocystis pyrifera*) several times per month. Care was taken to prevent cross contamination between tanks, including submersing gloved hands, measuring tools etc. in a tamed iodine solution (Prepodyne) and spraying surfaces with 70% ethanol as necessary. Animals were tagged by inserting either a numbered stainless steel washer on stainless steel wire or a numbered vinyl sleeve (Floy Tag, Seattle) on a cable tie through the first and second most recently formed respiratory pores. Benzocaine (Sigma, 40 mg/L, 15 min baths) was used as an anesthetic to dislodge animals for transfer or treatment.

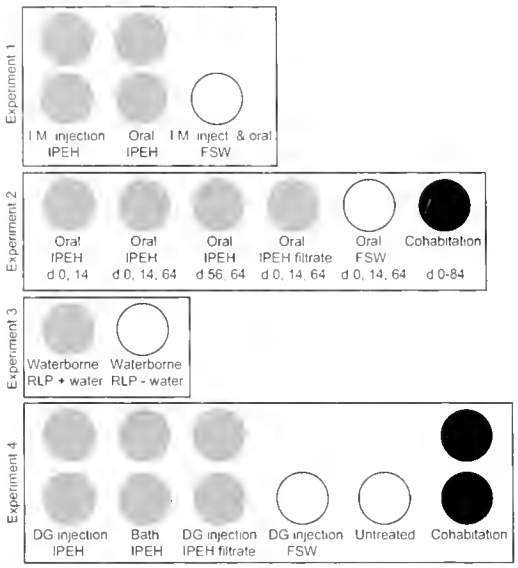

Figure 1. Schematic diagrams of the experimental units in Experiments 1 through 4. Circles represent the numbers of tanks in each treatment group, with experimental tanks shaded, negative control tanks white and positive control tanks black. The first line of text indicates the method of delivery of the material shown in the second line of text. For Experiment 2 the third line of text shows the days on which animals were treated; the first group was sacrificed at day 28 and the remainder on day 84. IPEH: RLP-infected black abalone postesophagus homogenate; FSW: Filtered seawater; DG: Digestive gland.

Histology: Quantification of RLP Infection Intensity and WS Signs

Animals that died during each experiment and all survivors at experiment termination were processed for histological detection of RLP burden. Animals in Experiment 4 were also assessed for WS-associated pathomorphological changes in the digestive gland and foot. Tissue sampling and histological processing was performed as previously described (Moore et al. 2000). Davidson's-fixed (Shaw & Battle 1957), hematoxylin and eosin-stained 5 μm paraffin tissue sections containing postesophagus, digestive gland, foot muscle, kidney and gonad were prepared for each animal, and slides were encoded to prevent bias during assessment. RLP infection intensity was estimated for the postesophagus and digestive gland (the two tissues in which RLPs can be found at high densities, Friedman et al. 2000). RLP burdens were quantified in each tissue using the scale of Friedman et al. (1997) based on the average number of RLP inclusions per 200× magnification field of view: absent = (0), 1–10 = (1), 11–100 = (2), or greater than 100 = (3). Four different disease signs of withering syndrome were assessed using integral scales from 0–3, modified from Moore et al. (2000). For all four parameters, (0) represented a normal healthy appearance. For body shrinkage, (1), (2) and (3) represented slight, moderate and severe shrinkage respectively; for digestive gland metaplasia or digestive gland atrophy, (1), (2) and (3) denote 5%–10%, 11%–25%, and greater than 25% of the digestive gland being comprised of transport duct epithelia or connective tissue, respectively. Foot degeneration scores of (1), (2) and (3) denote muscle fibers comprising 76%–90%, 51%–75% and less than 50% of the foot muscle, respectively. A condition index, CI = total weight, g/(shell length, cm)^3, was also used to assess body shrinkage. The presence of the renal coccidian *Pseudoklossia haliotis* (Friedman et al. 1995) was also noted.

Preparation of Infected Postesophagus Homogenate (IPEH)

Experiments 1, 2 and 4 attempted transmission of the WS-RLP using several methods of delivering homogenized, RLP-infected postesophagus tissue excised from adult black abalone (IPEH). Black abalone donor animals were collected from Vandenberg Air Force Base, California, where WS has been endemic since approximately January 1994 and RLP prevalence was approximately 90% during the collection period (C. S. Friedman & J. D. Moore, unpublished observations). Animals were collected several times per year during 1996–1998, held in 9–13°C seawater and fed kelp *ab libitum*. Postesophageal tissue (including the "crop" as described by Bevelender, 1988) from three to eight animals was pooled and minced in 0.2 μm filtered seawater (FSW) on ice. The tissue was homogenized with a 7-ml Tenbroeck homogenizer. The tissue homogenate contained large pieces of connective tissue and other debris which were removed by gentle centrifugation (100-250 × *g* for 2–5 min). The clarified homogenate was transferred to a new tube and diluted with FSW as necessary to obtain required volumes as described below.

Experiment 1: RLP Transmission by Intramuscular Injection or Oral Inoculation

In July 1997, black abalone were collected from Sobranes Point (Carmel), California, a location where WS had not been observed. One month after collection, the animals were randomly distributed to 5 tanks (4–5 abalone per tank) and acclimated from 14°C to 19°C over 1 wk. The treatment groups are shown in Figure 1. The IPEH consisted of 1.745 g of postesophagus from four black abalone diluted to 15 ml. The IPEH was administered at a rate of 6.8 μl IPEH/ g whole animal weight to four animals in each of two duplicate tanks by either intramuscular injection in the foot with a 23-gauge needle or oral delivery using a 23 gauge animal feeding tube inserted into the mouth. A single tank (n = 5 animals) served as a negative control; animals were treated with both oral delivery and intramuscular injection of FSW. All animals were sacrificed on day 60 post-initiation and examined for the presence of RLPs by histology.

Experiment 2: RLP Transmission by Oral Inoculation

In August 1997, black abalone were collected from Carmel Point (Carmel), California, where WS had not been observed. In March 1998 the abalone were randomly distributed into six tanks (n = 6 animals/tank). Temperatures during the experiment ranged from 11.5°C–15°C until day 40, after which temperatures were elevated to 17°C–20°C, with an overall mean ± s.d. of 15.6°C ± 2.8°C. Treatments (Fig. 1) consisted of multiple oral inoculations with IPEH or a 0.2 μm filtrate of IPEH at a rate of 3.0 μl/g whole animal weight on days 0, 14 and 64 post-initiation. The IPEH on each day of treatment consisted of 5.2–7.5 g of postesophagus from three or four black abalone brought to a volume of 15 ml with FSW. To prepare IPEH filtrate, IPEH was centrifuged (400 × *g*, 5 min) and then filtered twice through 0.2 μm syringe filters. As a positive control, three black abalone from Vandenberg Air Force Base were added to one tank of the Carmel Point abalone and maintained until termination of the experiment. On day 56, after discovering negative results in the IPEH treated group that was sacrificed at day 28, a previously untreated group was inoculated with a more concentrated IPEH (2.8 g postesophagus in 5 ml FSW without centrifugation). One IPEH treated group was sacrificed at day 28 and all other groups were sacrificed on day 84 post-initiation and examined for the presence of RLPs by histology.

Experiment 3: Waterborne RLP transmission

In March 1998, adult red abalone were collected by scuba from Caspar Cove and Mill Cove, Mendocino County, California where WS had not been observed. In August 1998, 14 animals were divided equally into two groups and placed in 8-L tanks. Each of the two tanks was connected to its own intermediate 8-L tank by approximately 25 cm of tubing. The inflow to the intermediate tank of one treatment was connected to an 18°C water source (= control). The inflow to the other intermediate tank was connected to the outflow of a 30-L tank that contained approximately 60 RLP-positive red abalone 2–10 cm in length and was supplied with the same seawater source. The animals were sacrificed 111 days post-initiation and examined histologically for the presence of RLPs.

Experiment 4: WS Development Following RLP Transmission by Digestive Gland Injection or Bath Exposure

Experiment 4 utilized animals from the same collection as Experiment 3. In July 1998 one hundred animals were tagged, equally distributed among ten tanks and allowed to acclimate for 29 days, during which period the water temperature was raised from 15°C to 18°C. Animals were treated on days 0, 21, 35, 56, 91 and 109 of the study with the treatments shown in Figure 1. On each treatment date, IPEH was prepared from 6.5–7.9 g of postesophagus tissue excised from six to eight black abalone and brought to a final volume of 160 mL with FSW (FSW/3% heat-inactivated fetal bovine serum on day 0). The IPEH filtrate was prepared by successive filtration of IPEH through 8 μm, 0.8 μm, 0.2 μm and 0.1 μm filters, except on day 0, when 0.1 μm filters were unavailable and the 0.8 μm filtrate was put through 0.2 μm filters twice. For all digestive gland injection treatments (FSW, IPEH, IPEH filtrate), animals were injected with 3.6 μL/g whole animal weight in the posterior ventral portion of the digestive gland using a 23 gauge needle. Recipient animals ranged in weight from 221 g to 1,360 g resulting in injection volumes ranging from 0.8 ml to 4.9 ml. For the bath treatment, tanks were drained and brought to a volume of 30 L, to which 25 mL of IPEH was added. Tanks were then maintained statically with aeration for two hours, after which flowing seawater was returned. The cohabitation positive control replicates were each supplied on day 0 with three Vandenberg black abalone showing variable degrees of body shrinkage. Black abalone that died were replaced until day 104, at which time all black abalone were removed.

After the discovery that an animal in the IPEH filtrate treatment that died on day 91 was infected with the RLP, a decision was made to inject these animals with antibiotics. This was based on the design of this treatment to allow a potential viral pathogen to infect recipients in the absence of the RLP. These abalone were injected in the foot with oxytetracycline (10 mg/ml in 2% saline) at a rate of 21 mg/kg tissue weight. Injections were made every 48 h for a total of three injections, followed by two to three weeks without injections and repeating the series two more times for a total of nine injections over 47 days.

Five feeding trials were conducted to measure the amount of kelp consumed by abalone in each treatment. An amount of kelp equal to 15% of the total body weight in each tank was added with the amount remaining after 24 h being reclaimed and weighed.

The experiment was terminated on day 446 post-initiation when mortality in the bath treatment approached levels seen in the cohabitation and IPEH injected groups. Statistical analysis of the results from Experiment 4 included a Chi Square contingency table analysis comparing IPEH injected, IPEH bath, cohabitation and IPEH filtrate-injected treatment groups to the negative control group ($\alpha = 0.05$). Data for WS signs (body shrinkage, digestive gland metaplasia, digestive gland atrophy or foot degeneration) were condensed into low (score of 0–1) or high (score of 2–3) categories of severity and 2 × 2 contingency tables compared observed vs. expected frequencies in each treatment group and the negative control group. Similarly, frequencies of low vs. high levels of each WS sign were compared in animals with low-level RLP infections (RLP intensity score 0–1) vs. high level infections (RLP intensity score 2–3) for the postesophagus and digestive gland separately. When the frequency in any cell was less than five observations a Fisher Exact test was employed.

RESULTS

Experiments 1 and 2: RLP Transmission by Intramuscular Injection or Oral Inoculation

In Experiment 1, 60 days after a single injection or oral inoculation with infected black abalone postesophagus homogenate (IPEH) or filtered seawater, one individual that received IPEH orally contained a single focus of two RLP inclusions in the postesophagus (RLP intensity = 1). In Experiment 2, no RLPs were seen among the six animals sacrificed at day 28. Upon termination at day 84, RLPs were detected in postesophagi of two of the six individuals orally inoculated with non-clarified IPEH on days 56 and 64, and in one individual in the FSW-injected negative control group. The RLP inclusions in these animals were small and very infrequent (RLP intensity = 1). Five of the six cohabitation positive control animals had low RLP intensity scores (RLP intensity = 1 in postesophagus, digestive gland, or both) and in one animal no RLPs were detected.

Experiment 3: Waterborne RLP Transmission

Histological analysis of survivors in each tank at day 111 revealed the RLP to be present in 100% (6/6) of the animals receiving effluent from the RLP-positive tank, while those receiving direct-source seawater had no RLP infections (0/6). One animal in each tank died prior to termination and in each case tissues were too necrotic for histological analysis. Intensities of postesophagus and digestive gland infections in the six RLP-positive animals ranged from relatively mild (1) to severe (3).

Experiment 4: WS Development Following RLP Transmission by Digestive Gland Injection and Bath Exposure

No significant difference in condition index was observed between tanks at day 0 (ANOVA, $p = 0.29$) and only one individual (in one of the replicates to receive IPEH by bath treatment) showed slight body shrinkage. Mortality in the group injected in the digestive gland with IPEH began during wk 27 and reached 90% at termination (Fig. 2). Mortality began during wk 33 in the tanks to which infected black abalone were added (positive control) and cumulative mortality also reached 90%. Mortality in the IPEH bath treatment group began during week 35 and steadily increased to 70% by termination of the study. Nearly all of the animals that died in the positive control, IPEH injected and IPEH bath treated groups showed signs of WS and the presence of RLPs (see below). One animal in the control, FSW-injected group was sacrificed on day 44 post-initiation due to morbidity related to shell damage. Microscopic examination of stained tissue sections indicated an absence of RLPs in this animal. One animal in the IPEH filtrate-injected group was sacrificed on day 91 post-initiation due to the presence of an extensive shell fungal lesion (not seen in any other animals throughout the experiment). Histological examination indicated the presence of several small foci of RLP inclusions in the postesophagus. An antibiotic treatment regimen was initiated in this treatment group to eliminate any possible infections in the remaining animals. This allowed for continuity of the treatment group as a test for whether the pathogen causing WS could be a viral agent. Several wk before termination of the experiment two animals died in the negative control treatment group and histological examination revealed an absence of RLPs.

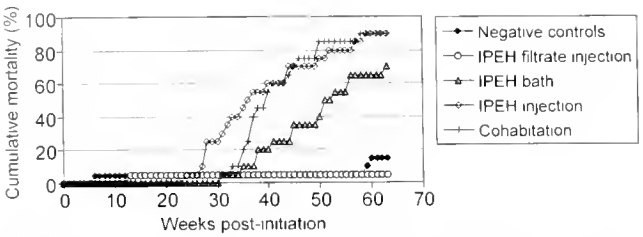

Figure 2. Cumulative mortality in Experiment 4. Treatment groups consist of duplicate tanks containing ten abalone each; the negative controls group consists of one tank of untreated abalone and one in which digestive glands were injected with filtered seawater. IPEH: RLP-infected black abalone postesophagus homogenate.

Nearly all of the animals that died had moderate to severe signs of WS. Figure 3 illustrates that mean values for body shrinkage, digestive gland metaplasia, digestive gland atrophy and foot degeneration were all higher for animals that died than those that survived. Coinciding with these elevated signs of WS, animals that died had mean RLP burdens more than four times those of survivors (RLP intensity = 2.3 ± 1.0 vs. 0.50 ± 0.8 in postesophagi, 1.8 ± 1.0 vs. 0.30 ± 0.6 in digestive glands for animals that died vs. survivors respectively, mean ± s.d.).

Histological examination of survivors of the experiment revealed that eight of the nine animals in the untreated negative control tank contained RLPs, including seven with mild infections (RLP intensity = 1 in postesophagus, digestive gland, or both) and one with a moderate infection (RLP intensity = 2 in both the postesophagus and the digestive gland). One of the tanks of IPEH filtrate-injected animals contained an individual with a light RLP infection of the postesophagus. Table 1 indicates that, despite these

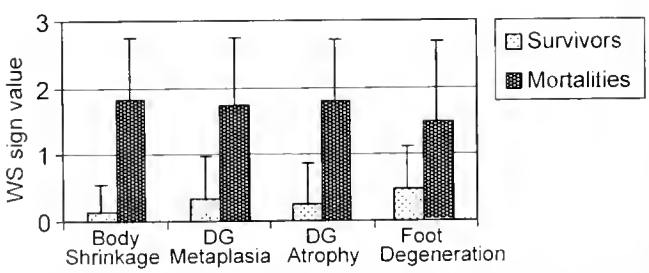

Figure 3. Severity of signs of WS in survivors and animals that died in Experiment 4. The range for each sign was from 0 (normal, healthy) to 3 (severe) (see Methods). DG: Digestive gland. Mean + s.d.

TABLE 1.

Experiment 4, mean values for RLP infection intensity and WS signs in duplicate tanks of each treatment.[1]

Treatment	Postesophagus RLP Intensity	Digestive Gland RLP Intensity	Digestive Gland Metaplasia	Digestive Gland Atrophy	Foot Degeneration	Body Shrinkage	Condition Index
Negative controls[2]	0.9, 0	0.6, 0	0.1, 0.5	0.5, 0.5	0.3, 0.9	0.3, 0.3	0.155, 0.173
IPEH filtrate injection	0, 0.2	0, 0	0.1, 0.1	0, 0.1	0.1, 0.4	0, 0.2	0.148, 0.159
IPEH bath	2.1, 1.6	1.4, 1.7	1.1, 1.8	1.3, 1.4	0.6, 1.3	1.0, 1.3	0.130, 0.131
IPEH injection	2.2, 3.0	1.5, 2.2	1.7, 2.2	1.6, 1.9	1.5, 2.2	1.9, 2.3	0.108, 0.115
Cohabitation	2.2, 2.4	1.8, 1.9	1.6, 1.6	1.7, 1.8	1.2, 1.6	1.2, 2.1	0.104, 0.122

[2] First replicate = animals injected with filtered seawater, second replicate = untreated.

infections, the negative control and IPEH filtrate-injected groups had dramatically lower RLP infection intensities and signs of WS than the IPEH bath, IPEH injected and positive control groups. The mean values for RLP burden and all WS signs were highest in the cohabitation positive control group and IPEH injected group, and lower in the IPEH bath treatment group (Table 1). Table 2 shows the results of contingency table analyses comparing RLP burdens and severity of WS signs in the treatment and positive control groups to the negative controls. The IPEH injected, IPEH bath and cohabitation exposures resulted in significantly increased RLP infection intensity and severity of WS signs while the IPEH filtrate injected animals were not different from the controls.

The relationship between WS signs and RLP burdens was addressed by comparing the severity of WS signs in animals with different RLP infection intensities. Figure 4 illustrates that animals with higher RLP burdens had more severe signs of WS. This association was statistically examined by contingency table analyses which compared the frequencies of low vs. high RLP burdens in animals having low vs. high levels of WS signs. Body shrinkage, digestive gland metaplasia, digestive gland atrophy and foot degeneration all showed highly significant relationships with postesophagus and digestive gland RLP infection intensities ($p < 0.001$ for all comparisons).

The amount of food eaten on a per-weight basis by the animals in each tank was measured at five time points during the experiment. By wk 30 post-initiation, the amount of kelp eaten by the cohabitation and IPEH injection groups was lower than that of the other groups (Fig. 5). These low rates remained fairly consistent over time as severely affected animals died and others developed more severe signs of WS. Feeding rates in the IPEH bath treatment group declined prior to onset of mortality with high RLP burdens.

The renal coccidian, *Pseudoklossia haliotis* was present in only five animals with no relation to treatment across all treatment groups.

DISCUSSION

Withering syndrome appears to be directly caused by a gastrointestinal Rickettsiales-like prokaryote that has been designated "*Candidatus Xenohaliotis californiensis*" (Friedman et al. 2000). These studies demonstrate that the organism can be transmitted by experimental methods and that successful transmission appears requisite for development of WS in previously healthy red abalone.

Despite rigorous preventative efforts, we experienced apparent contamination of tanks with the RLP or the inadvertent use of infected recipient animals, as evidenced by discovery of the RLP in negative control animals in Experiments 2 and 4. In Experiment 2, the single positive animal in the FSW-administered negative control group may have resulted from infection prior to collection from the wild population; 15 months after collection of the animals in this experiment the RLP was found in a high percentage of animals at a nearby site (C. S. Friedman & C. A. Finley, unpublished observations). The two animals inoculated with IPEH that were found to be RLP-positive could have acquired infections by that treatment or via the method of the contaminated control animal. In Experiment 4, infections in the untreated negative control tank apparently developed very late in the study and were likely due to recent contamination from adjacent tanks, equipment, water

TABLE 2.

Experiment 4, significance values for Chi Square or Fisher Exact tests using dichotomous categories for each parameter (scores of 0 or 1 vs. 2 or 3) and comparing treatment groups shown to negative control groups.[1,2]

Treatment	Postesophagus RLP Intensity	Digestive Gland RLP Intensity	Survival[3]	Digestive Gland Metaplasia	Digestive Gland Atrophy	Foot Degeneration	Body Shrinkage
IPEH filtrate injection	1.0	1.0	0.605	[4]	0.231	0.487	0.487

source or food supply. The water source (BML) and site of kelp collection (Bodega Bay) are believed to have been RLP-free throughout the study period. The two animals in one tank of the IPEH filtrate-injected treatment of Experiment 4 could have obtained infections via the routes noted above or by passage of the RLP through the filters used to create the filtrate. As commonly reported for RLPs of molluscs, "*Candidatus Xenohaliotis californiensis*" is pleomorphic with spherical to rod-shaped forms. The smallest diameter of the rod-shaped form measured 145 nm (Friedman et al. in press) and therefore the RLP may have passed through the 0.2 μm filters used on day 0.

Evidence for the RLP being the Etiologic Agent of WS

Our experiments clearly show that the agent of WS was present in RLP-infected black abalone postesophagus tissue homogenate (IPEH). Although contamination of negative control tanks prevents concluding with certainty, the dynamics of infection and mortality in the bath and injection treatments of Experiment 4 indicate that the RLP infections and WS signs were due to our experimental transmission. The onset of mortality in the IPEH-injected group before the cohabitation group suggests that this experimental treatment was more effective in transmitting the WS-associated pathogen than natural exposure. Furthermore, the lack of expression of WS in animals receiving injections of the IPEH filtrate, in contrast to those receiving unfiltered IPEH, indicate that the etiologic agent of WS is probably not a virus. These observations, considered with the relationships between RLP intensity and severity of WS signs, provide strong evidence linking the RLP directly to WS.

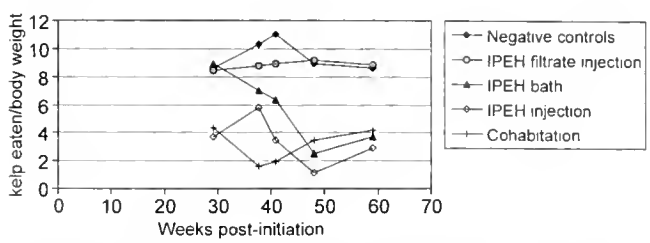

Figure 5. Relative feeding rates of Experiment 4 treatment groups measured at five timepoints. Each point is the average of values for two tanks. Abscissa scale is equal to that of Figure 1. IPEH: RLP-infected black abalone postesophagus homogenate.

WS Signs

Body shrinkage, foot muscle atrophy and to some extent digestive gland atrophy are generic signs of starvation and not specific to WS. Shrunken abalone with soft flesh have been reported in association with apparent poor food supply or environmental conditions (Young 1964, MacGinitie & MacGinitie 1966) and diseases other than WS (Nakatsugawa et al. 1999). In contrast, digestive gland metaplasia, in which functional tissue including secretory cells is replaced with cells similar in appearance to those of transport ducts, appears to be pathognomonic for WS. One fascinating aspect of this alteration is that the RLP infects duct-like tissue of the digestive gland and not terminal tubules; thus, infection with the RLP results in morphological changes which provide more tissue of the type which the pathogen can infect. Moore et al. (2000) recently reported that WS-positive animals ate less than animals without overt signs of the disease. Based on those findings we initiated feeding studies during wk 29 of Experiment 4, and the five trials suggest that a sharp drop in feeding rate precedes death in animals with signs of WS. These observations suggest that although the RLP results in pathologic changes to gastrointestinal epithelia, malabsorption resulting from these changes is not solely responsible for body shrinkage, and decrease in the ability or desire to consume food also plays a role. Diminished feeding rate may be one of the earliest indicators of adverse health in animals that acquire withering syndrome.

RLP has Low Host Species Specificity

Transmission of the RLP by cohabitation of black abalone donors and recipients was reported by Friedman et al. (this volume). Our Experiment 2 had similar results and Experiment 4 showed for the first time that the agent can be transmitted by cohabitation of black abalone donors and red abalone recipients, while Experiment 3 demonstrated transmission between red abalone. These findings agree with a wealth of morphological (Friedman et al. 1997, Moore et al. 2000), ultrastructural (Friedman et al. 2000, C. S. Friedman & J. D. Moore, unpublished observations) and DNA-based studies (Andree et al. 2000, Antonio et al. 2000) indicating that the RLP found in red and black abalone does not differ between species. RLPs identical in appearance and tissue location by histology have also been observed in California green (*H. fulgens*) and pink (*H. corrugata*) abalone (C. S. Friedman, unpublished observations).

Modes of RLP Transmission

Intramuscular injection and oral inoculation were investigated as methods of transmitting the RLP in Experiments 1 and 2. Lack of detection of the RLP following intramuscular injection agrees with observations that infected tissue appears to be completely restricted to specific cell types in the epithelium lining the digestive tract. However, Gulka and Chang (1984) reported successful transmission of a gill epithelium-specific RLP in the scallop *Placopecten magellanicus* by intramuscular injection of the adductor muscle with RLP-infected gill homogenate. The limited success of oral inoculation in our experiments may have been affected by their short duration (60 and 84 days for Experiments 1 and 2 respectively), since histological detection of the RLP was based on examination of a single 5 μm tissue slice for each potentially

affected organ. Prior to this study, transmission of the RLP had only been achieved by cohabitation. Abalone are gregarious animals, and during cohabitation frequently come in direct physical contact with each other. The results from Experiment 3 suggest that transmission of the RLP can survive in seawater and does not require close contact for transmission.

Many if not all Rickettsiales-like prokaryotes of marine invertebrates and fish are capable of direct horizontal transmission from host to host. This is in contrast to most Rickettsiales-like organisms with mammalian primary hosts, which require a parasitic arthropod host for dispersion (Marchette & Stiller 1982). The requirement for parasitic arthropods (lice, ticks, fleas) for transmission of mammalian RLPs is related to their lack of a sporogonic stage and incapability of surviving desiccation. Ingestion of RLP-contaminated food is likely the predominant mode of RLP transmission in the marine environment. Transmission of *Piscirickettsia salmonis* has been reported for coho salmon held in aquaria with infected conspecifics for one month (Cvitanich et al. 1991). Horizontal transmission of RLPs by feeding infected tissue of conspecifics has been reported for 'Stained prawn disease' of *Pandalus platyceros* (Bower et al.1996) and for transmission of an RLP from the red shrimp *Penaeus marginatus* to the blue shrimp *P. stylirostris* (Brock et al. 1986). Ingestion of contaminated food as a mode of pathogen entry and fecal/oral spread as a mode of dispersal are likely operative for the RLP associated with withering syndrome in abalone.

We found that injecting the digestive gland with infective material was an efficient mode of transmission of the RLP. Sites of injection healed rapidly with no associated morbidity or mortality. The digestive gland of abalone is a large organ containing transport ducts that are host tissue for the RLP. These open into the stomach, which receives food from the postesophagus, while the distal portions lead to terminal tubules where nutrient absorption and enzyme secretion occur (Bevelender 1988, Campbell 1965, Voltzow 1994). Among IPEH-injected animals, 16 out of 18 animals for which histological sections of both organs were available had RLPs present in both the digestive gland and postesophagus, indicating that the infections were able to spread from the former to the latter tissue. In the remaining two animals the RLP was detected in postesophagus and not digestive gland tissue, possibly due to the pathogen spreading to the postesophagus before spreading completely throughout the digestive gland. Thus, our studies provide further evidence that '*Candidatus Xenohaliotis californiensis*' is the etiologic agent of WS, a disease capable of affecting multiple haliotid species.

SYMBIONTS OF CULTURED RED ABALONE *HALIOTIS RUFESCENS* FROM BAJA CALIFORNIA, MEXICO

JORGE CACERES-MARTINEZ* AND GISSEL D. TINOCO-ORTA

Centro de Investigación Científica y Educación Superior de Ensenada, Laboratorio de Patología de Moluscos, Departamento de Acuicultura Ensenada, Baja California, México

ABSTRACT Although the commercial culture of the red abalone *Haliotis rufescens* started in Baja California in 1993, no descriptions of the symbionts of this species exist. To determine which symbionts were associated with cultured red abalone in the Bahía de Todos Santos, Baja California, we conducted a survey of apparently healthy and moribund abalone. Apparently healthy abalone were larger (34 mm) than the moribund abalone (25 mm). Two polychaetes belonging to Spionidae and Serpulidae were found on the shell, although no serious damage was observed in relation to these worms. The renal coccidian *Margolisiella* (= *Pseudoklossia*) *haliotis*, was prevalent in 72% of the moribund and 10% of apparently healthy abalone. Rickettsiales-like prokaryotes (RLPs) associated with the withering syndrome (WS) were found in the epithelia of the digestive gland of all moribund abalone, 84% of apparently healthy abalone were also infected with RLP, although no clinical signs were observed. Ciliate protozoa were observed in the lumina of the esophageal pouches of both apparently healthy (78% prevalence) and moribund animals (57% prevalence). Other ciliates were observed on branchia and within the branchial cavity of apparently healthy abalone (17%) and moribund abalone (88% prevalence). Although there was a trend for greater prevalence and intensity of symbionts in moribund compared to apparently healthy abalone, the differences were not significant.

KEY WORDS: red abalone, symbionts, Rikettsiales-like prokaryotes, *Margolisiella* (*Pseudoklossia*) *haliotis*, withering syndrome, aquaculture

INTRODUCTION

In Baja California, México, abalone culture is a promising industry that has increased in magnitude over the past years (Flores et al. 1995). Successful aquaculture requires a knowledge of the symbionts of the cultured species, and which of these may present a risk for the cultured animals. More than 20 species of abalone symbionts have been recorded around the world (Table 1). The pathogenicity of symbionts varies from none to severe, and some symbionts are opportunistic pathogens (see references in Table 1). Withering syndrome (WS) is an emerging disease that affects the black abalone *Haliotis cracherodii* and red abalone *Haliotis rufescens* (Friedman 1991, Culver & Richards 1992, Friedman et al. 1993, Friedman et al. 1995, Friedman et al. 2000). The renal coccidian *Margolisiella* (= *Pseudoklossia*) *haliotis* (Dresser & Bower 1997) was first investigated as a possible causal agent of the fatal syndrome. However, no correlation was found between the WS and infection by the coccidian (Friedman et al. 1995). Lately, a prokaryote belonging to the order rickettsiales (Rickettsiales-like prokaryotes, RLP), which has been identified provisionally as "Candidatus *Xenohaliotis californiensis*", is now considered the causal agent of WS (Friedman et al. 2000). Another symbiont that has emerged as an important pest of the red abalone, *H. rufescens* cultured in California, is the introduced sabellid worm *Terebrasabella heteronuncinata* (Fitzhugh & Greg 1999), which has caused significant damage to the abalone industry (Oakes & Fields 1996, Kuris & Culver 1999). Since there have been no studies on the diseases and symbionts of abalone in México, we investigated the diseases (particularly the withering syndrome) and symbionts of apparently healthy and moribund abalone from a culture facility. In addition, we examined empty shells for external symbionts and signs of disease.

MATERIALS AND METHODS

The culture of red abalone was carried out in a protected area of the inner side of Islas de Todos Santos, one of the two islands located at the mouth of the Bahía de Ensenada (31°45′–31°59′ N, 116°36′–116°45′ W). The culture system consisted of plastic net cages suspended from floating long-lines supported by 200 L plastic barrels (Flores et al. 1995). In December 1997, 21 apparently healthy and 30 moribund abalone, and 313 empty shells were collected randomly from the bottom of a culture cage where some mortality was observed, for examination (this facility is not in operation anymore). These abalone were progeny of brood stock imported from California.

The total shell length of all abalone and empty shells was measured. In addition, the total weight (TW) including visceral, muscle, and the meat weight (MW) including visceral mass, were recorded to obtain a condition index of apparently healthy and moribund abalone. The condition index (CI) was measured as the ratio of the meat weight to total weight (MW/TW) (Friedman et al. 1997). Values obtained were grouped as suggested by Friedman et al. (1997): (1) healthy abalone with CI of $\geq$ 0.6, (2) slightly shrunken abalone with a CI from 0.55 to 0.59, and (3) severely atrophied animals with a CI < 0.55.

The inner and outer shells were checked for epibionts under a dissecting microscope. The prevalence of symbionts was estimated as the number of infested abalone/number of abalone examined ×100. Serpulid infestation was qualified, according to the percentage of shell surface covered, as low (1 to 25%), medium (26 to 50%), or high (51 to 75%). Shell blisters caused by burrowing worms (*Polydora*) were also counted.

The visceral mass of the abalone was fixed whole in Davidson fixative (Shaw & Battle 1957) for at least 24 hours. Four transverse sections containing portions of the digestive tract (posterior esophagus included), kidney, muscle and gills, were processed for paraffin histology. Deparaffinized, 5μm sections were stained with iron hematoxylin, eosin, fuchsin acid and aniline blue (Gray 1954). The degree of renal coccidian infection was estimated at 200× magnification and ranked in accordance with Friedman et al.

Interaction level: – negative, 0 neutral, ? unknown. –/0 negative or neutral depending on the infestation degree.

(1997): (1+) no coccidia, (2+) 1–10 coccidia per field of view, (3+) 11–100 coccidia per field, (4+) 101–1000 coccidia per field and (5+) >1000 coccidia per field. Similarly, RLP infection intensities were ranked according to the number of bacterial foci into the following categories: (1+) no RLP, (2+) 1–10 RLP, (3+) 11–100 RLP, (4+) 101–1000 RLP and (5+) > 1000 per field of view at 200× magnification. The appearance of the digestive gland was also quantified following similar criteria to Friedman et al. (1997). A score of (1+) was given if tissues were normal (Bevelander 1988), (2+) if moderate degeneration of the tissues was observed, and (3+) for severe degeneration of the tissues. Protozoa in the esophageal pouch and gill branchiae were counted from each histological preparation.

RESULTS

The mean shell length (±SE) of apparently healthy abalone was 34.4 mm (±1.03), whereas that of moribund animals was 25.9 mm (±0.67) and empty shells 24.0 mm (±0.2). An ANOVA comparing the means indicated no significant difference in shell length between moribund abalone shells and empty shells, although these groups' shells were significantly smaller than those of apparently healthy abalone (Student-Newman-Kleus, $P < 0.001$). Apparently healthy abalone were active, responded to tactile stimulation, while the color and consistency of their foot muscle were considered normal. Moribund abalone were weak, retracted and had a flaccid foot muscle. They also showed slow tactile responses.

Analysis of the shell revealed the presence of two polychaete symbionts, one belonging to the family Serpulidae (spirorbids), and the other to the Spionidae, probably from the genus *Polydora*. The spirorbids formed calcareous tubes on the external surface of the shell. Respiratory holes were not occluded and neither deformation of the shell, nor perforations toward the internal side of the shell were caused by these worms. They were present on all observed shells (in all groups), shell coverage ranging from medium to high. The prevalence of spionids in healthy abalone was 10% with an intensity of 2 worms per host; in moribund abalone, prevalence was 7% with an intensity of 1.5 (±SE 0.12), and in empty abalone shells prevalence was 7.3% with an intensity of 2.5 (±SE 32).

The histopathological study revealed the presence of macrogametes (Fig. 1a) and microgametes (Fig. 1b) of a renal coccidian parasite in the left and right kidneys. Coccidia were present in 72% of moribund and 10% of healthy abalone. The degree of infection in the moribund group ranged from moderate to heavy (4–5+) whereas it was moderate (4+) in apparently healthy abalone.

RLPs were found in the epithelial cells of the digestive tract, including the posterior esophagus, digestive diverticuli (Fig. 2a) and intestine. They were present in all moribund animals and 84% of the apparently healthy abalone. Apparently healthy abalone infected by RLP showed no detectable clinical signs of the WS. The degree of infection in moribund animals ranged from mild to heavy (3–5+), and 64% of them showed degeneration of the digestive gland ranging from moderate (2+ in 28%) to severe (3+ in 72.2%). In heavily infected animals, expelled inclusion bodies were found in the lumina of the digestive tract (Fig. 3b). In contrast, 31% of the apparently healthy infected abalone presented only mild digestive gland degeneration (2+). Apparently healthy abalone weighed significantly more than moribund abalone (6.62 g SE ± 0.54 vs. 1.84 g SE ± 0.11 respectively, *t*-test, $P < 0.001$). The condition indices of apparently healthy abalone (0.6) were higher than those recorded for moribund abalone (0.34), but were similar between apparently healthy without and with (0.6) RLP infections (Kruskal Wallis test, $H = 31.6$, $P < 0.001$ and Dunn's pairwise multiple comparison method $P < 0.005$). These condition values correlated with degeneration of the digestive gland observed in moribund animals.

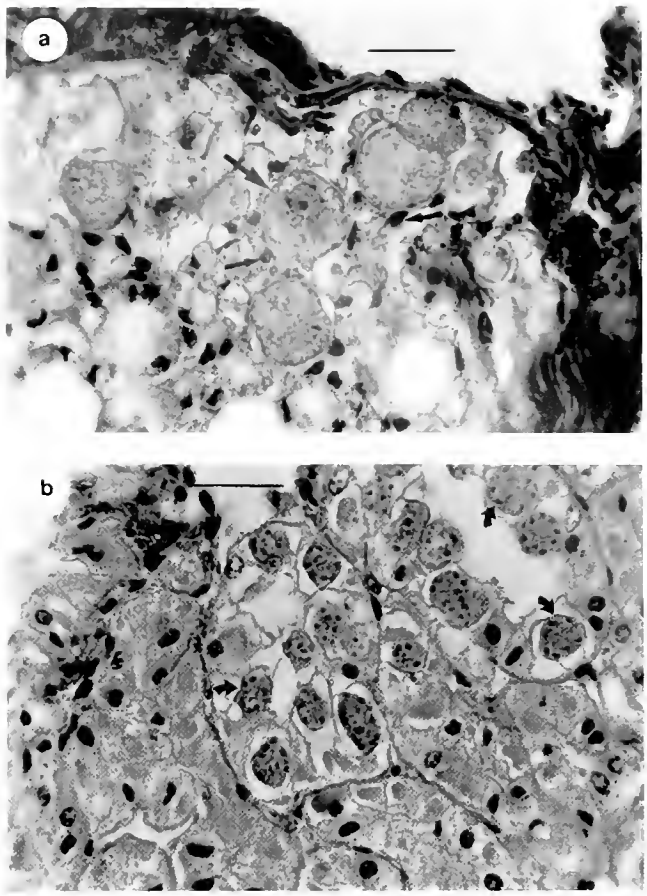

Figure 1. (a) Macrogametes of *Margolisiella* (*Pseudoklosia*) *haliotis* (large arrow) in the left kidney of a healthy abalone. Small arrows are showing hemocite around the parasite. (b) Microgametes of *M. haliotis* (arrows) in the right kidney of a moribund abalone. Scale bar = 20 μm.

A ciliate protozoan with a granular endoplasm and large vacuoles was found in the lumen of the esophageal pouches (Fig. 3a, b). The unidentified ciliate was pleomorphic and measured 40 × 12 to 90 × 19 μm. The ciliate was occasionally observed in contact with the epithelial cells of the esophagus, but was generally free in the lumen of the esophageal pouches. Prevalence in apparently healthy abalone was 78%, compared to 57% in moribund abalone. The maximum intensity of the protozoan in histological sections was 330 (mean 50.9 ± SE 18.8) in apparently healthy abalone and 120 (mean 24 ± SE 10.1) in moribund abalone (Mann-Whitney Rank sum test, $P > 0.05$).

Other ciliates of different sizes were observed in the branchial cavity and among the lamellae of the branchia (Fig. 4a). These organisms contained a granular cytoplasm with large vacuoles (Fig. 4b). Their prevalence in healthy abalone was 17% compared to 88% in moribund abalone. The maximum intensity of this pro-

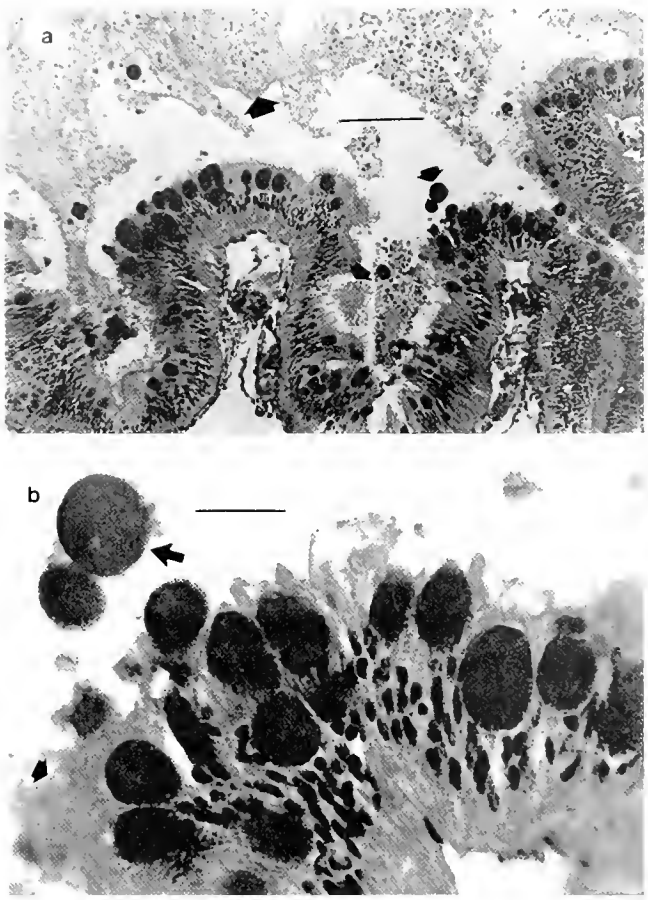

Figure 2. (a) Rikettsiales-like prokaryotes in the post-esophagus epithelial columnar cells of an infested moribund abalone. Note rupture of some columnar cells, (arrow in the middle), expelled RLP (arrow), and great quantity of mucus and hemocytes in the lumen of the post-esophagus (big arrows). Scale bar = 125 µm. (b) A close up of the infected epithelium and some expelled bacterial foci (big arrow) and rupture in the epithelium (small arrow). Scale bar = 20 µm.

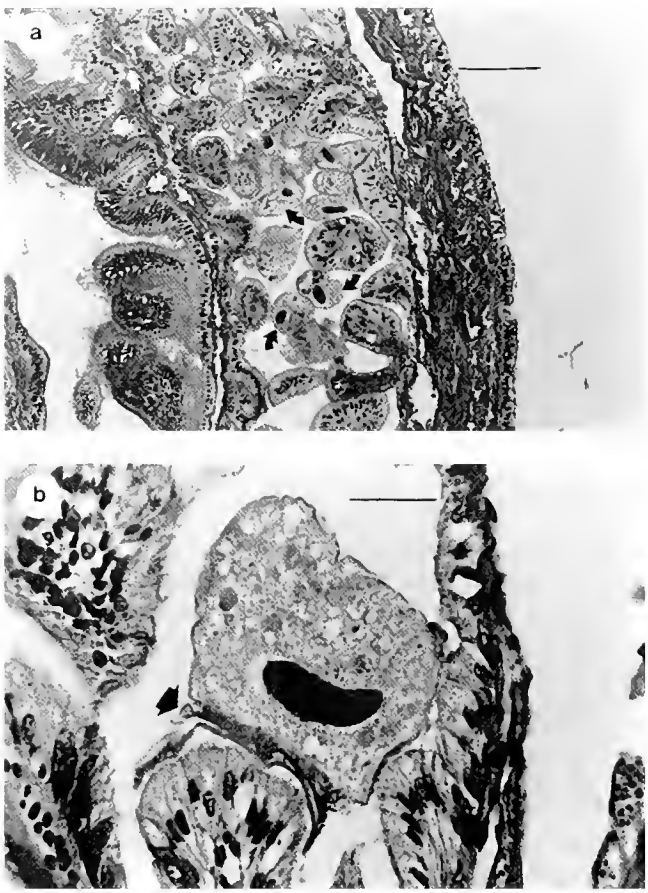

Figure 3. (a) Protozoans (arrows) in a healthy abalone's esophagous pouch lumen. Note that there is apparently no reaction of the host. Scale bar 80 µm. (b) Close up of a protozoan touching the epithelial cells of the esophagous pouch. Scale bar = 20 µm.

tozoan in healthy abalone was 21 (mean 10.2 ± SE 4.1), compared to 85 (mean 30.3 ± 6.7) in moribund abalone, although the differences were not significant (*t*-test, $P > 0.05$).

DISCUSSION

Although symbionts of wild and cultured abalone populations in California have been widely documented (Friedman 1991, Haaker et al. 1992, Lafferty & Kuris 1993, Davis 1993, Oakes & Fields 1996, Friedman et al. 1997, Shields & Perkins 1997), this is the first health evaluation of cultured red abalone from Baja California. We found the presence of a disease and several symbionts similar to those recorded in abalone from California. This is in accordance with the fact that the culture of red abalone in Baja California depends on the importation of brood and seed stock from California. Comparison of the diseases and symbionts of the cultured abalone with local red abalone populations in the wild was not possible due to the scarcity and difficult accessibility of these natural populations. These difficulties explain the need for importing red abalone from California.

There is no information on the possible effect of *Polydora* spp. in small and thin shells of young red abalone. In oysters, mussels and clams the polychaete complex, *Polydora-Broccardia*, results in loss of condition, indirect high mortality and economic losses (Lauckner 1983, Handley & Berguist 1997). Several members of the complex have been observed in *Haliotis* spp. (Hansen 1970, Blake 1996, Handley & Berguist 1997). Contrary to Clavier (1989) who reported that *H. tuberculata* smaller than 50 mm were not infested by *Polydora* spp., we found burrowing worms in individuals smaller than this size. Serpulids are commonly attached to pilings, floats, algae, mussels (Abbott & Reish 1980) and infested abalone, although they apparently do not represent any risk. There was no evidence of presence of the sabellid polychaete *Terebrasabella heterouncinata* which Fitzhugh and Greg (1999) report infests abalone in California.

Margolisiella (= *Pseudoklossia*) *haliotis* has been recorded in the black abalone *H. cracherodii*, red abalone *H. rufescens*, blue-green abalone *H. fulgens* and pinto abalone, *H. kamschatkana* (Friedman et al. 1993, Friedman et al. 1995). This coccidian has a broad geographic range that includes Bahía de Todos Santos México and the California coast. It does not seem to be lethal to these host species. This coccidian has been discounted as a causal agent of WS (Friedman et al. 1993, Friedman et al. 1995, Friedman et al. 1997). The prevalence of coccidia recorded in moribund abalone (72%) was similar to those found in abalone from central and southern California (Friedman et al. 1997). A lower prevalence and intensity of infection in apparently healthy abalone compared to moribund abalone may be coincidental. However, further

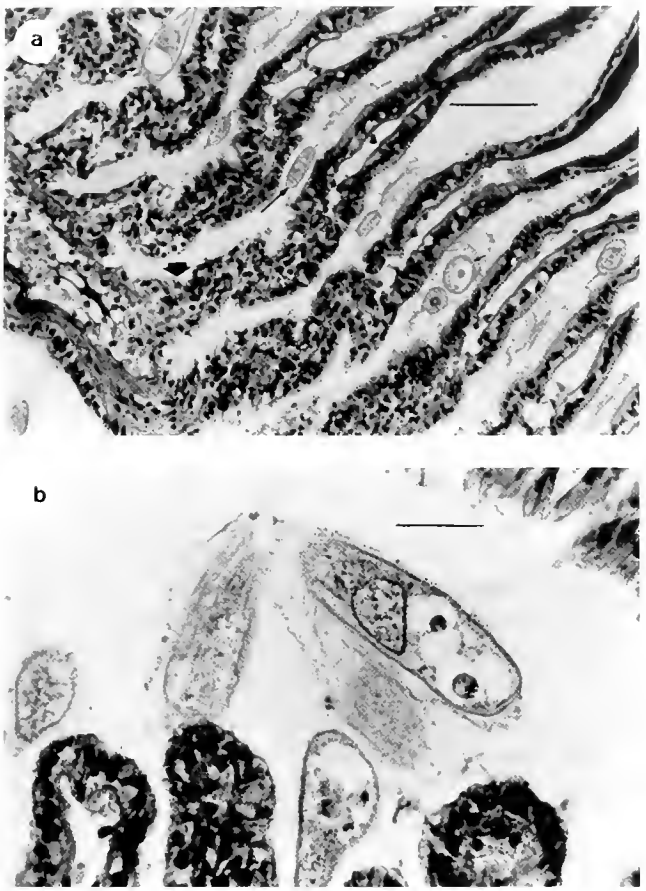

Figure 4. (a) Several ciliated protozoa (thin arrows) among the branchial filaments of a moribund abalone. Note the necrotic zones in the branchial filaments (wide arrow). Scale bar = 100 µm. (b) A close up of ciliated protozoa around the branchial filaments of a moribund abalone. Note the large nucleus and vacuoles in the protozoan. Scale bar = 20 µm.

studies on alterations in abalone physiology in relation with renal coccidia are needed.

The presence of RLP in cultured Mexican stocks of red abalone must be considered in the aquaculture facilities management and sanitary practices. The majority of the observations of WS in the red abalone were reported from laboratory/aquaculture facilities in California (Moore et al. 2000). Friedman (1995) reported that during a survey of abalone for WS in California, from 1 to 4% of the red abalone from San Miguel Island had visual signs of WS. Moribund abalone in our studies were characterized by retracted visceral tissues, discoloration and shrunken appearance of the foot muscle, low condition, presence of RLP in the digestive gland and some degeneration of the digestive gland, suggesting that these abalone were affected by WS. A similar situation has been reported by Moore et al. (1999) who associated dramatic mortality of red abalone from aquaculture facilities with the WS. Withering syndrome in black and red abalone has a long incubation period (5–7 months and 7–8 months respectively), before clinical signs are visible (Friedman et al. 1997, Moore & Friedman unpublished results cited by Friedman et al. 2000). Hence, RLP infected individuals are undetectable by visual condition. The degree of infection in asymptomatic but infected abalone was similar to those found in moribund abalone and could be explained by susceptibility differences among individuals and incubation period. Our sampling was carried out during the 1997 El Niño when temperature was 2°C above normal in the area. High water temperatures have corresponded with increased mortality of RLP-infected black abalone (Friedman et al. 1997). Undoubtedly, more thorough and detailed studies (using large samples) concerning RLP infection in different abalone species, and studies focusing on the identification and differentiation of RLP species or strains associated with abalone species are needed.

The similar prevalence and total numbers of ciliates from the esophageal pouches in healthy and moribund abalone found in the present study suggest a commensal symbiosis. Further taxonomic and biological studies are needed to determine the species of this protozoan and the nature of the symbiosis.

Vanblaricom et al. (1993) recorded the presence of suctorian ciliates in gill squashes and mantle scrapings of healthy black abalone and those apparently afflicted by the WS. Presence of these ciliates did not relate to clinical signs of the disease in the host abalone. A considerable number of ciliates has been associated with marine bivalves and the majority of these appear to be harmless commensals (Lauckner 1983). In this study, similar prevalence of ciliates in apparently healthy and moribund abalone suggested that these organisms are not related to the moribund condition of some of the abalone examined. An increase in total numbers of protozoans on the gills coincides with host weakness and death (Lauckner 1983) which may be due to the saprozoic habits of some species (Kudo 1982).

Abalone from Baja California have almost the same symbionts species as those in California. This highlights that it is necessary to maintain a continuous monitoring program to avoid introduction of new potentially dangerous symbionts to the region.

ACKNOWLEDGMENTS

Rebeca Vásquez-Yeomans and Sergio Curiel Ramírez helped us in processing the samples and in data analysis. James D. Moore, from Bodega Marine Laboratory sent us a histological slide of a red abalone in order to compare our results. This project was supported by project number 623106-CICESE.

ABSTRACT The California abalone aquaculture industry has been struggling to rid itself of an exotic sabellid, *Terebrasabella heterouncinata* following its inadvertent introduction from South Africa in the late 1980s. The development of an effective management strategy is dependent upon understanding the life history of this sabellid, including its fertilization strategy (e.g. self-fertilization) and its generation time. In the present study, red abalone, *Haliotis rufescens* Swainson 1822, with single sabellid infestations were isolated in containers at 18°C (single host and sabellid per container). This first, parental generation (P), was held in isolation until individuals produced F_1 larvae. The F_1 larvae were subsequently isolated until individuals produced a second, F_2, generation. In a separate study, uninfested red abalone were exposed to sabellid infested abalone at 11.2°C, 15.6°C, and 20.9°C, temperatures typically encountered in California. The larvae were subsequently observed as they developed to specific life stages: the initiation of feeding, the development of all 11 setigers (which closely relates to sexual maturation) and the completion of their life cycle as recognized by the production of motile, infesting, larvae. Approximately 50% of the sabellids examined at 11.2°C, 15.6°C, and 20.9°C had developed the ability to feed by day 6, 5 and 4 ($P < 0.001$), had developed all 11 setigers by day 83, 68 and 48 ($P < 0.001$) and had produced larvae by day 298, 165 and 111 ($P < 0.001$), respectively. This research demonstrates that isolated individuals do pose the threat of producing fully functional offspring and that the generation time of *T. heterouncinata* is significantly temperature dependent.

KEY WORDS: sabellid, abalone, life history, self-fertilization, *Terebrasabella*

INTRODUCTION

The California abalone aquaculture industry is presently struggling with two serious diseases, one of which is an introduced sabellid polychaete, recently described as *Terebrasabella heterouncinata* (Fitzhugh & Rouse 1999). This sabellid was cited by California growers as their most serious "problem and constraint," reporting that the reduced growth rates and negative public perception associated with the worm were having a substantial negative impact on the industry (Mcbride 1998). *Terebrasabella heterouncinata* is believed to have been introduced from South Africa in the late 1980s, via the importation of infested research abalone (Kuris & Culver 1999, Ruck & Cook 1998). Concern exists regarding the threat that the sabellid poses to the California cultured abalone industry and to native gastropod populations if it were to become established within the state's intertidal ecosystem (Kuris & Culver 1999). Presently, there is one documented case of *T. heterouncinata* infestations in gastropods (snails and limpets) adjacent to a culture facility (Kuris & Culver 1999). Broad-scale removal of infested hosts, combined with clean-up efforts at the culture facility may have curtailed the sabellid from becoming permanently established in the intertidal environment (Kuris & Culver 1999).

Infestations occur by the unique ability of *T. heterouncinata* to overcome the host abalone's defenses and settle upon the under side of the leading edge of the shell. Normal shell deposition is disrupted as the host attempts to cover the irritant with nacre. In heavily infested abalone, the deposition of the prismatic shell layer all but ceases, resulting in the domed shell found in association with the reduced growth rates (Culver et al. 1997, Kuris & Culver 1999, Ruck & Cook 1998).

Attempts to control *T. heterouncinata* in commercial settings have included manipulations of water temperatures, the coating of abalone shells with wax, quarantine of infested stocks, and improved sanitation practices (Oakes & Fields 1996, Oakes et al. 1995, Leighton 1998). Many of these techniques have been met with limited success, allowing low-level infestations to persist. Suggested new treatments include novel therapeutic delivery systems using micro-encapsulation (Ruck & Cook 1998, Shields et al. 1998) and the use of ultrasound (Loubser & Dormehl 2000). Unfortunately, none of these techniques, to date, have been successfully applied in a culture setting.

The initial description of *T. heterouncinata* noted that individuals were simultaneous hermaphrodites, but did not indicate if they were functional hermaphrodites, capable of self-fertilization. Upon settling at the 7th setiger stage, the sabellids are covered with nacre by the host resulting in the passive formation of what becomes the adult's tube. Development is characterized by the formation of a branchial crown and four additional setigers. As the 11th setiger is formed, an alteration of the type of uncini on the 6th setiger also occurs, both events occur as individuals are recognized as sexually mature (Fitzhugh & Rouse 1999). Spermatogenesis occurs in the 8th setiger and oogenesis occurs in both the 9th and 10th setigers. The mature adult broods several embryos within its tube for an unknown, temperature dependent, amount of time. The embryos eventually mature and develop into motile larvae that subsequently emerge from the tube of the adult and seek a suitable area of attachment (Fitzhugh and Rouse, 1999).

In the following study we examined the fertilization strategies and the life history of *T. heterouncinata*. We investigated if an isolated sabellid is capable of reproduction through two generations. We assessed the reproductive capabilities of *T. heterouncinata* by quantifying generation times at three water temperatures that reflect the range of temperatures encountered in California.

MATERIALS AND METHODS

Animals and Husbandry

Commercially reared red abalone, *Haliotis rufescens* Swainson 1822, that measured 15–25 mm in shell length, were purchased from or donated by culturists in California. All animals were held in the Pathogen Quarantine Facility at the Bodega Marine Laboratory, Bodega Bay, California. All effluent produced at this facility is chlorinated (>10 ppm Cl^- for 2–3 h) and dechlorinated prior to release. Animals were reared in flow-through, full strength, sand-filtered seawater. Experiments were conducted at average mean temperatures of ambient (12.6°C), heated (15.6°C, ~18°C and 20.9°C) or chilled (11.2°C) seawater. All abalone were fed *Macrocystis pyrifera* Agardh 1820, *ad libitum* and remained under artificial light on a 12-hour dark, 12-hour light cycle for the duration of these experiments. Strict sanitation protocols were followed to insure that no cross-contamination occurred.

Single Infestations Trial 1

Fifty uninfested red abalone were placed into a 10-l container with five red abalone, heavily infested with *T. heterouncinata*, for 24 hours. The newly infested abalone were inspected with a dissecting microscope 48 hours post-exposure and infestations were quantified. Fourteen abalone with single sabellid infestations were removed and individually isolated in 200-ml containers. Four abalone, that had multiple sabellid infestations per abalone, were isolated in a similar manner to serve as positive controls. Four uninfested abalone were isolated in a similar manner to serve as negative controls. All 22 containers received ambient seawater, ~12.6°C, and were randomly placed on a wet table.

Abalone were sampled every 14 days by gently pushing aside the epipodium and mantle tissue and inspecting the leading edge of the shell for the presence of recently settled larvae. Following the discovery of new larvae, treatments were sampled every seven days. Uninfested abalone were added to any container in which the original infested host abalone had died, providing live hosts for larval settlement. The abalone were observed for a total of 32 weeks, at which point the sabellids that had not produced larvae were carefully dissected from their tubes and observed under dissecting and compound microscopes to determine if signs of reproduction were visible.

Single Infestations Trial 2

Forty uninfested red abalone were exposed to *T. heterouncinata* infested abalone as described in Trial 1. Abalone were inspected 48 hour post-exposure and the infestations were quantified. Four abalone with single parental (P) generation infestations (Fig. 1) and four uninfested abalone (negative control) were removed and individually isolated in 700-ml containers. Animals were visually inspected weekly. Sabellid larvae settle preferentially on live hosts (C. A. Finley & C. S. Friedman, unpublished observation). To allow F_1 larvae to settle only on recipient, sabellid-free abalone, infested (P host) abalone were sacrificed after 60 days post-exposure and a single uninfested abalone (larval recipient) was placed into each tank with the infested shucked shells. Once a recipient abalone became infested with an F_1 larva, the newly infested animal was removed and isolated (single abalone with single sabellid) in a 700-ml container. Additional uninfested abalone were added to the containers with the P generation sabellids to attain multiple individuals with single F_1 infestations (Fig. 1).

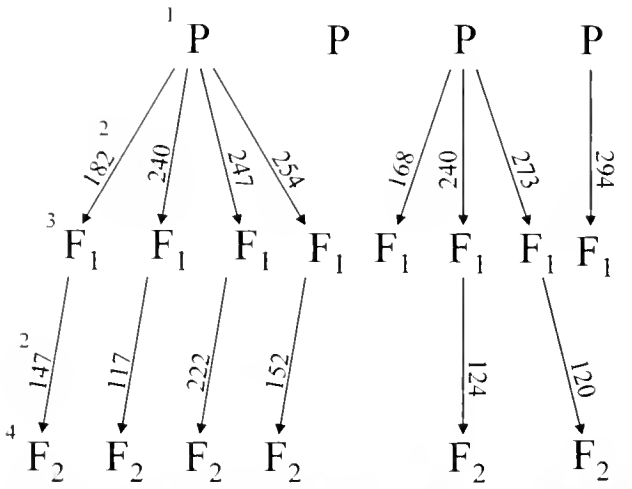

Figure 1. Individual abalone from single infestation trial 2. Two successive generations of sabellids and the number of days until offspring were produced is illustrated. Superscripts (1–4) indicate (1) the parental generation, (2) the number of days until larvae were observed, (3) the F_1 larvae produced by the parental by the parental generation and (4) the F_2 larvae produced by the F_1 generation.

Host abalone containing F_1 larvae were visually inspected for signs of F_2 larvae. All containers received heated seawater (~18°C) for the duration of this trial. The abalone were observed for a total 497 days, at which point any sabellids that had not produced larvae were carefully removed and observed for signs of reproduction.

Life History Trial

Terebrasabella heterouncinata infestations were achieved by commingling 200 uninfested and 20 infested (10 live and 10 shucked) red abalone in a 10-l container for a 24 hour period. Following the exposure the 200 newly infested abalone were divided into three replicates tanks. Exposures were conducted at 11.2°C, 15.6°C, and 20.9°C. Infestations were quantified 48 hours after the end of the exposure period. The removal of the 20 heavily infested donor abalone marked time zero and every subsequent 24-hour period was regarded as an additional day of development.

Development to the following three life stages was recorded: the ability to feed, the development of the full complement of setigers and the production of infestive, motile larvae. Replicates were sampled every 24 hours for the first eight days, followed by weekly sampling. At each sampling point, six sabellids were removed from each replicate by sacrificing the host abalone and gently breaking up the shell with a scalpel.

The ability to feed was determined by providing the sabellids with suspended stained lipid beads (LBs). Following the protocol of Shields et al. (1998) microencapsulated, sudan black-stained, tripalmatin lipid beads that ranged in size from 3 to 30 μm were produced. Several abalone, with a total of six sabellids, were removed from each replicate tank and placed into three 200-ml containers to which 0.3 g of the lipid beads were added. The seawater-lipid bead suspension was stirred every 10 minutes. After 30 minutes, the abalone hosts were sacrificed and the sabellids were excised and examined for the presence of LBs in the digestive tract using a light microscope. We enumerated the number of feeding sabellids, terminating the LB exposures when all sabellids in a given replicate were able to feed.

To identify the development of all 11 setigers, six sabellids

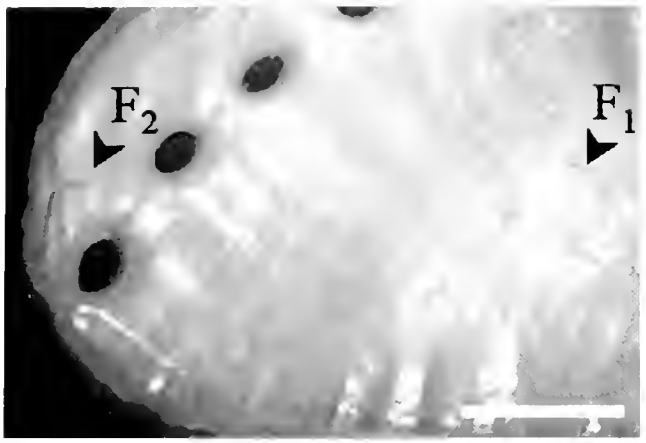

Figure 2. Abalone shell showing both the F_1 and F_2 generation. Bar = 5mm.

were removed weekly from each tank and the number of setigers was enumerated using a light microscope at 600× magnification. When 100% of the sabellids sampled from each replicate had developed a full complement of setigers, sampling was reduced to once every 1–4 weeks depending on the number of sabellids remaining and the temperature under investigation.

The completion of the life history of *T. heterouncinata* was defined by the production of either a motile, infesting larva or by a recently settled larva. Sabellids were excised as above and the presence or absence of motile or newly settled larvae was recorded. The experiment terminated when 100% of the sabellids inspected from each replicate completed their life cycle.

Statistical Analysis

With the assumptions of an ANCOVA not being met, an alternative way to analyze the data was needed. Linear regression lines were calculated for each replicate. The number of days that it took 50% of the sabellids to reach a developmental stage (T_{50}), was then calculated from the regression line using the formula $Y = bX + a$, setting the dependent variable, Y, equal to 50% and solving for X. The T_{50} estimates were then compared using one-way analysis of variance (ANOVA).

The data from the replicates at each temperature were also pooled and the number of days that it took for 50% of the sabellids to reach a developmental stage was calculated. The T_{50} estimates from the pooled replicates at a given temperature were then presented as the best estimate for the number of days post-settlement required for 50% of the sabellids to reach a given developmental stage at each temperature.

RESULTS

Single Infestations Trial 1.

Larval production by six of the 14 individually isolated sabellids began during weeks 26 to 32 (Table 1). Of the seven sabellids that had not produced any larvae, three contained well-developed internal eggs, one contained both internal and external eggs and embryos, and the remaining three tubes were devoid of sabellids at the termination of Trial 1. One abalone was contaminated by the effluent from another tank and was discarded.

Abalone with multiple sabellid infestations (positive control) also began producing larvae during week 26. Sabellids on 3 of the 4 abalone produced larvae (Table 1) and only vacant sabellid tubes were found on the fourth animal at the termination of Trial 1. No sabellid infestations were found on the negative control animals (Table 1).

Single Infestations Trial 2.

Three of the four P generation sabellids produced an F_1 generation. The first larva was observed on day 168 (Fig. 1). Subsequently, two of the P generation sabellids produced additional F_1 larvae (three and four, respectively). Six of the F_1 generation produced an F_2 generation. The first larva appeared 117 days after the F_1 parent had settled (Fig. 1). Figure 2 illustrates a host shell with both F_1 and F_2 sabellids.

Life History

Recently settled larvae that had fed on stained lipid beads were easily distinguished from individuals that had not fed (Fig. 3). The amount of time required for the sabellids to develop the ability to feed increased significantly as the temperature decreased (ANOVA, $p < 0.001$). The pooled replicates indicated that 50% of the sabellids reached this developmental stage at 20.9°C, 15.6°C, and 11.2°C by 3.7, 4.9 and 6.0 days post exposure, respectively (Fig. 4).

The rate at which the sabellids developed a full complement of setigers was also affected by temperature. The number of days required for the sabellids to develop all 11 setigers required significantly more time as the temperature decreased (ANOVA, $p < 0.001$). Analysis of the pooled data indicated that 50% of the newly settled larvae developed a complete complement of setigers at 20.9°C, 15.6°C, and 11.2°C by 47.7, 68.4 and 83.1 days post exposure, respectively (Fig. 5). The majority of the sabellids observed had developed both eggs and sperm in conjunction with the development of all 11 setigers.

The number of days required for the sabellids to produce motile, infesting larvae or newly settled larvae required significantly more time as the temperature decreased (ANOVA, $p < 0.001$). Analysis of the pooled data indicated that 50% of the newly settled larvae had completed their life history at 20.9°C, 15.6°C, and 11.2°C by 110.8, 165.0 and 297.8 days post exposure, respectively (Fig. 6).

DISCUSSION

Self-fertilization is not considered the predominant mode of fertilization for many simultaneous hermaphrodites due to the del-

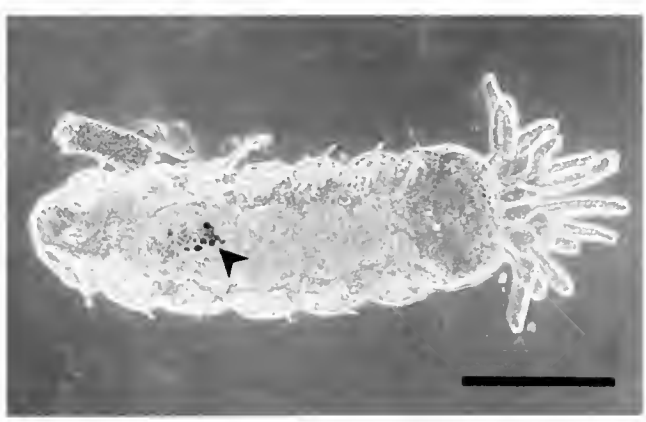

Figure 3. A juvenile sabellid with lipid-stained beads visible in the digestive tract (arrow). Scale bar = 100 µm.

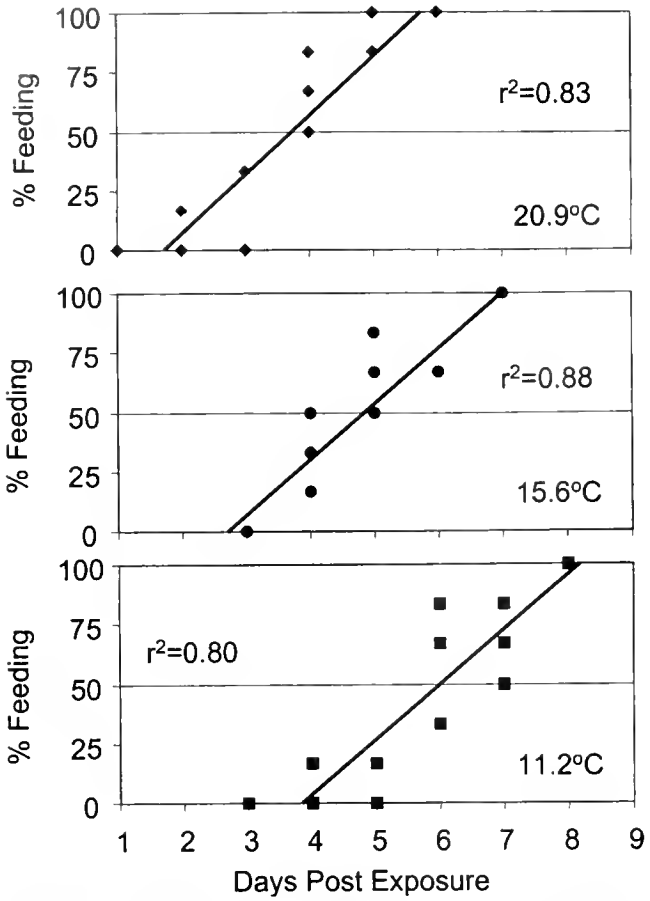

Figure 4. Percentage of feeding sabellids in pooled replicates at each of three temperatures investigated. Regression lines indicate that 3.7, 4.9 and 6.0 days post-exposure, 50% of the sabellids had developed the ability to feed at 20.9°C, 15.6°C, and 11.2°C, respectively.

eterious effects believed to be associated with inbreeding (Heath 1977, Beckwitt 1982, Michiels & Streng 1998). There are, however, several examples of successful self-fertilization among marine invertebrates (Ghiselin 1974, Beckwitt 1982, Knowlton & Jackson 1993, Scharer & Wedekind 1999), some of which include members of the class Polychaeta (Ghiselin 1969, Hsieh 1997). Hsieh (1997), for example, found no deleterious effects of self-fertilization in the simultaneous hermaphrodite *Laonome albicingillum*, also a sabellid polychaete.

Most polychaetes broadcast spawn small ova that are capable of being distributed great distances from the parent. In contrast, *T. heterouncinata*, produces a relatively small number of large eggs that are brooded within their tube and lack a pelagic stage. Combined, these characteristics make *T. heterouncinata* a likely candidate for self-fertilization (Knowlton & Jackson 1993). In addition, adult sabellids are sessile and rely solely upon their short infesting motile stage for the distribution of progeny to other hosts. Given this life history, one would predict that if the benefits of reproductive assurance associated with self-fertilization outweighed the deterrents of "selfing," the requirement of cross-fertilization would be selected against (Jarne & Charlesworth 1993). For a sessile parasite such as *T. heterouncinata*, that invests a relatively large amount of energy into a limited number of eggs combined with a lack of control over accessing a partner, self-fertilization would be a successful strategy to assure that a founding sabellid on a host abalone would remain capable of producing progeny.

Self-fertilization is one plausible explanation for the production of the F_1 and F_2 generations that we observed, though alternative fertilization strategies, such as parthenogenesis, cannot be ruled out. These experiments were designed to investigate whether a single isolated sabellid has the ability to produce functional progeny or if a minimum population number is necessary to assure cross-fertilization. Our research indicates that a single sabellid is capable of founding a viable population.

Following its accidental introduction in the late 1980's, *T. heterouncinata* was able to quickly spread throughout the state's farmed abalone industry. This rapid spread was due, in part, to the interdependency within the industry on seed transfers, in conjunction with the early misidentification of the sabellid as a native polychaete. Following the discovery of the sabellid as an exotic species, the California Department of Fish and Game (CDF&G) recognized the organism as a threat to the state's natural resources and aquaculture industry. In an attempt to control the further spread of the polychaete, the CDF&G, consulting with the industry-initiated Abalone Sabellid Worm Advisory Committee, developed a policy that all abalone transfers by farms be inspected and deemed to be sabellid-free (Aquaculture Disease Committee, July 6, 1995; Thoesen 1994). This sampling regime was selected, in part, because a minimum population density of sabellids was believed to be required to establish a viable population. Our research demonstrates that low-level infestations (or even a single founding

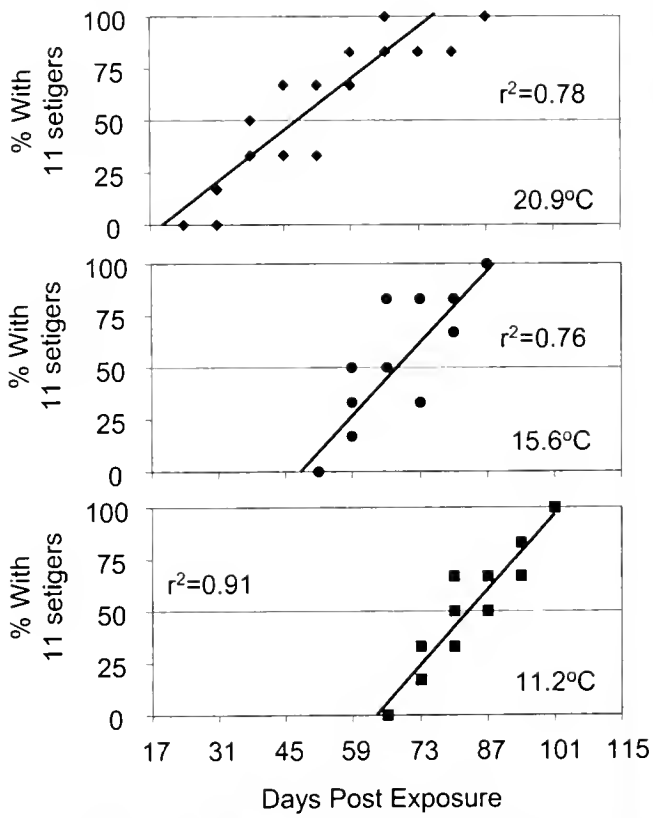

Figure 5. Percentage of sabellids that had developed a full complement of setigers (n = 11) in pooled replicates at each temperatures investigated. Regression lines indicate that 47.7, 68.4 and 83.1 days post-exposure, 50% of the sabellids had developed 11 setigers at 20.9°C, 15.6°C, and 11.2°C, respectively.

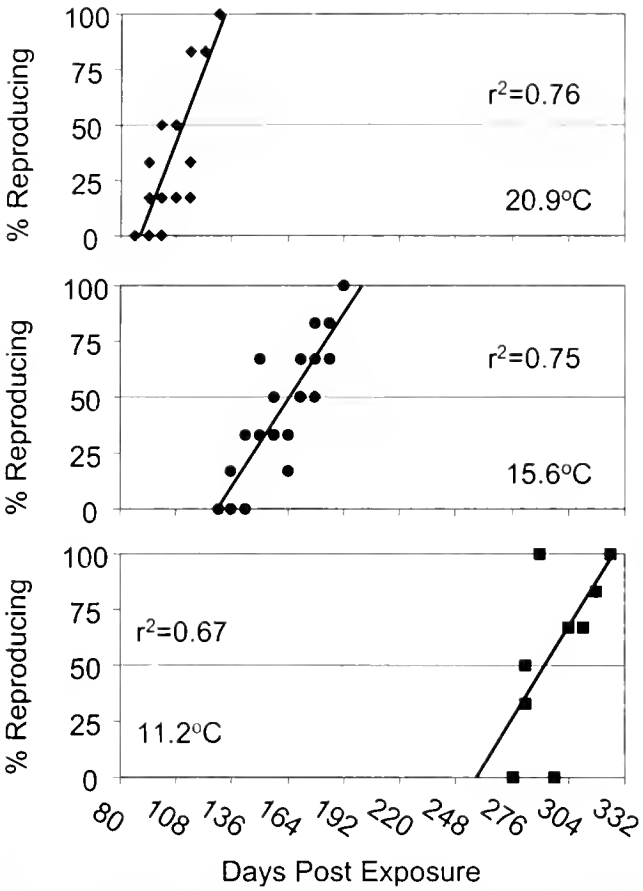

Figure 6. Percentage of sabellids that had produced motile, infestive larvae or newly settled larvae in pooled replicates at each temperature investigated. Regression lines indicate that after 110.8, 165.0 and 297.8 days, 50% of the sabellids had completed their life history at 20.9 C, 15.6°C, and 11.2°C, respectively.

sabellid) could pose a significant threat not only to the aquaculturist, but to the marine intertidal ecosystem.

Many polychaetes demonstrate positive relationships between environmental temperature, within the physiological ranges, and the rate at which they reach maturity (Cha et al. 1997, Olive et al. 1997, Qiu & Qian 1997, Qiu & Qian 1998). *Terebrasabella heterouncinata* appears to follow this trend. Previous research has reported that reproductive maturity in *T. heterouncinata* can occur in approximately one month (Kuris & Culver, 1999) or in three months (Ruck & Cook 1998) when animals were held at undefined ambient temperatures. Our controlled laboratory studies found that the most rapid development occurred at the highest of the three temperatures investigated (20.9 C), where average development of a full complement of setigers (n = 11) took 47.7 days. This decrease in time to maturity in association with elevated seawater temperatures would be expected to result in increased infestation levels, an observation that agrees with what has been experienced by California growers (B. Beede pers. comm.). Higher infestation levels are typically observed in the warmer waters of the southern part of the state, particularly in association with El Niño events.

Previous studies on polychaetes have demonstrated that at lower temperatures (again within physiological ranges) development would be prolonged, but that one would expect to observe a significant number of embryos and larvae developing into mature adults (Qiu & Qian 1997). Our research indicates that the development of all 11 setigers and the age at maturity is indeed prolonged at lower temperatures and would be expected to result in lower infestation levels. *Terebrasabella heterouncinata* does, however, appear to be capable of completing its life history at the lower temperatures encountered in the northern part of the state where annual averages range from 8–13°C (Mcbride 1998). This portion of the state should not be viewed as a thermal refuge from *T. heterouncinata*, although its life history will take longer to complete and less obvious, low level infestations, may result.

SHELL BORING CLAMS IN THE BLUE ABALONE *HALIOTIS FULGENS* AND THE YELLOW ABALONE *HALIOTIS CORRUGATA* FROM BAJA CALIFORNIA, MÉXICO

MA. DEL CARMEN ALVAREZ-TINAJERO,[1]* JORGE CÁCERES-MARTÍNEZ,[1] AND JOSÉ GUADALUPE GONZÁLEZ-AVILÉS[2]

[1]*Centro de Investigación Científica y de Educación Superior de Ensenada, Laboratorio de Patología de Moluscos, Departamento de Acuicultura, Ensenada, Baja California, 1 2732 México;* [2]*Sociedad Cooperativa de Producción Pesquera, Pescadores Nacionales de Abulón, Ensenada, Baja California, México*

ABSTRACT The blue abalone *Haliotis fulgens* and yellow abalone *Haliotis corrugata* support the major portion of the abalone fishery in Baja California, México. Abalone shells are marketable according to the quality of their shell, which is determined by the quantity and kind of epibionts, such as boring clams. In order to determine the extent of infestation by shell boring clams in these abalone species, shell samples from the commercial catch were obtained from Isla de Cedros, Baja California, and analyzed. Three shell boring species, *Lithophaga aristata*, *Lithophaga plumula* and *Pentella conradi*, were found infesting the blue abalone. The yellow abalone was infested by *L. aristata* and *L. plumula*. The prevalence and density of these two species were greater in the yellow abalone than in the blue abalone. The density of boring clams increased on older and consequently larger abalone shells (greater shell surface), although this trend needs confirmation. X-ray images revealed the severity of shell damage in heavily infested animals. The identification of different fishing areas that provide different quality abalone shell, due to their boring clams load, opens the possibility for determining management regulations for obtaining better shells for marketing.

KEY WORDS: boring clams, *Lithophaga* sp., *Pentella* sp., *Haliotis fulgens*, *Haliotis corrugata*, abalone

INTRODUCTION

The abalone fishery is one of the most important economic activities in Baja California, México. This is because of the great value of the foot muscle of the abalone as a delicacy for human consumption, and because of the beauty of its shell which is used in jewelry. Two species, the blue abalone *Haliotis fulgens* (Philipi 1845) and yellow abalone *Haliotis corrugata* (Gray 1828), support this fishery.

Abalone shells from Baja California are marketable according to their quality, which is closely related to epibionts load and shell appearance. Top quality shells are those that have less than 50% of shell surface covered by epibionts, and no dark spots and blisters on the inner surface. These shells are exported for jewelry to Taiwan, Korea and China, reaching a value of about US$1,500 per ton. Shells that have 50% to 80% of their external surface covered with epibionts, and blisters on their inner surface are worth around US$1,000 per ton. Shells that have >80% of their external and internal surface affected by epibionts are not exported, but are marketable locally at a low scale, reaching a value of US$750 per ton.

The abalone shell is an adequate substrate for a great variety and quantity of epibionts to settle on. Of these, the boring clams may produce severe damage, as their burrows may penetrate the inner shell of the abalone, causing the host to seal the hole internally with a leathery layer of conchiolin. Moreover, the abalone may secrete more nacreous material inside the bore site, forming a blister (Abbott & Haderlie 1980). Occasionally, a great blister may appear to be an irregular half-pearl, however, this is empty and of no marketable value. On the other hand, abalone may produce true pearls between the visceral mass and the inner shell as a reaction against foreign particles. These abalone pearls are sold locally as valuable and expensive souvenirs, but are not exported because they are rare.

There have been no studies investigating the possible association of boring clams with the abalone, even though these epibionts damage the abalone shell and thus negatively affect their marketability. In order to determine the identity and degree of infestation by shell boring clams in the blue and yellow abalone at Isla de Cedros, samples were obtained from a commercial catch. Infestation rate as a function of abalone age and shell surface area was examined.

MATERIALS AND METHODS

In November 1997, 38 blue abalone and 48 yellow abalone were collected commercially from the northern end of Isla de

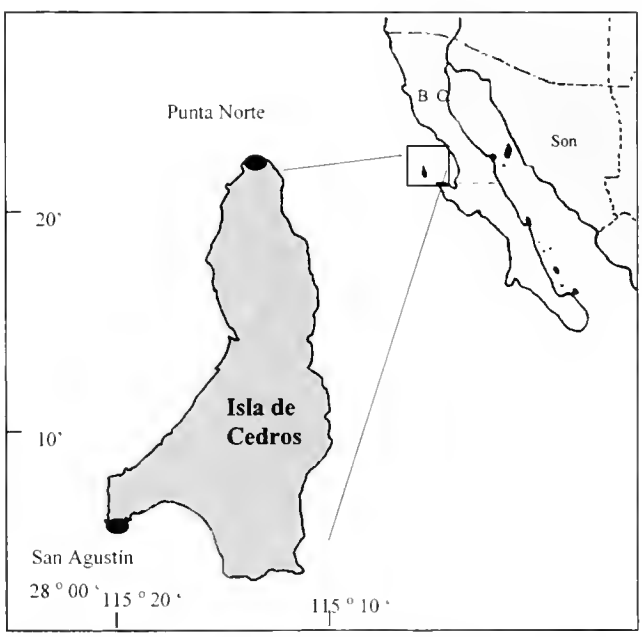

Figure 1. Sampling sites on the Isla de Cedros, Baja California, México.

Cedros (Punta Norte). A further 13 blue abalone and 21 yellow abalone were obtained from the commercial catch at San Agustin near the southern end of the island in June 1998 (Fig. 1). Abalone foot musele and viscera were detached from the shell, and the shell was numbered, cleaned and dried. The shells (Fig. 2) were examined under a stereoscopic microscope for the presence of boring clams, including blisters and spots of conchiolin deposition. All clams were extracted from the shell with the aid of dissection needles. Larger clams were measured with an electronic caliper; and the smallest, with a micrometer placed on the stage of a stereoscopic microscope. All clams were stored in dried vials and identified (Soot-Ryen 1955, Keen & Coan 1974, Haderlie & Abbott 1980).

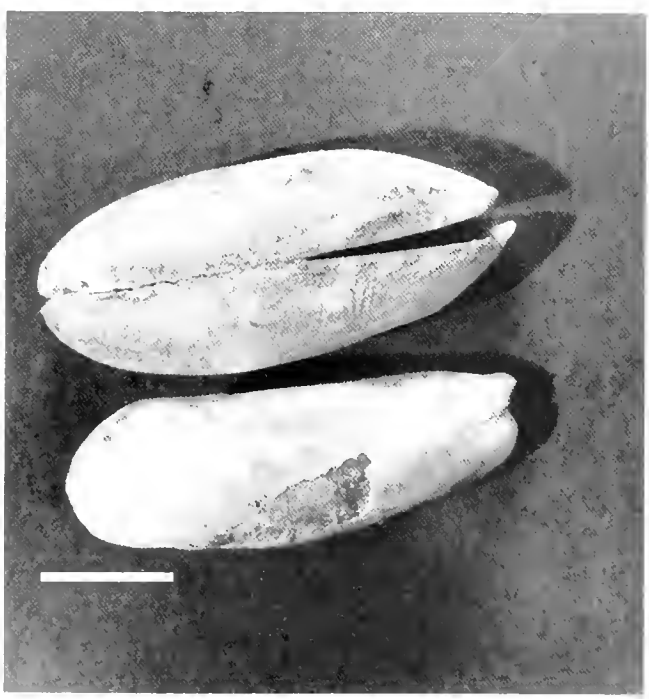

Figure 3. *Lithophaga aristata*, easily recognized by the crossing projections of the sculpture on the posterior part of the valves.

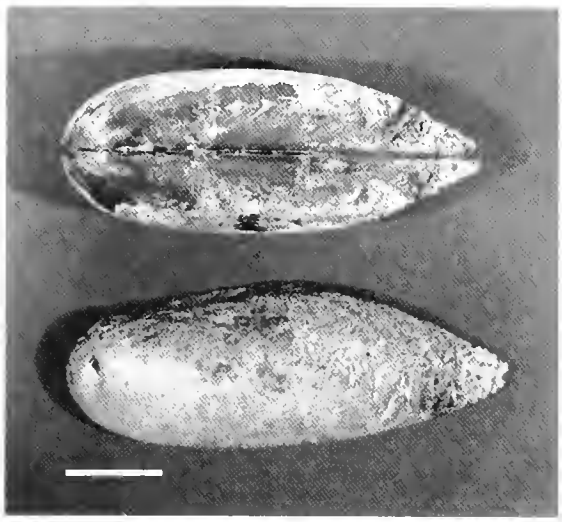

Figure 4. *Lithophaga plumula*, the most conspicuous character is the plume-like sculpture on the upper and posterior part of the valves.

The clams were grouped by species and size class to describe the composition of the epibiont clam population in the shell of each abalone species. Prevalence was estimated as the number of infested abalone/number of abalone examined ×100. Density (intensity) was recorded as the number of clams per cm^2 of abalone shell surface. The surface area of each cleaned abalone shell was estimated in the following way: aluminum foil was made to conform to the shape of abalone shells and all their irregularities. The foil was carefully cut, dried and weighed. Pieces of aluminum foil were weighed, obtaining the following least squares regression equation:

$$x = y - 0.0019/0.046$$

where

y = foil weight (g) and

x = area (cm^2); ($r^2 = 1$)

The surface of the abalone shells was calculated using the weight of the aluminum molds obtained.

The age of the abalone was estimated by polishing the spire zone of each shell and counting the prismatic growth lines (dark lines) in the spire under a stereoscopic microscope, according to the method of Shepherd and Avalos-Borja (1997) and Shepherd et al. (1995). A correlation analysis was used to determine the association between the age and shell surface area of each abalone shell, as well as the intensity of clam infestation.

A comparison was made between the density of the infestation determined by extraction of the clams from the abalone shell and that observed on x-ray plates.

RESULTS

Three shell boring clams, *Lithophaga aristata* Dillwyn 1817, *Lithophaga plumula* Hanley 1843 (family Mytilidae) and *Penitella conradi* Valenciennes 1848 (family Pholadidae) (Fig. 3, Fig. 4, Fig. 5) were found infesting blue abalone shells. Only *Lithophaga aristata* and *Lithophaga plumula* infested the yellow abalone. The holes made by the three boring clams were similar and some reached the inner side of the host shell. A leathery layer of conchiolin of irregular and variable size often formed a pustule that occluded the perforation. Nacreous material occluded old perforations forming irregular half-pearls. Table 1, Table 2 and Fig. 6 show the mean, minimum and maximum boring clam densities and prevalence found per abalone species and locality. *Lithophaga aristata* and *L. plumula* were the more abundant boring clams; *Penitella conradi* was very scarce. Table 3 shows a comparison (Mann-Whitney U test) between density per abalone species and locality. In general, *Haliotis corrugata* had a higher density of boring clams than *Haliotis fulgens*.

The mean size distribution of boring clams is shown in Fig. 7. Distribution of mean size class at Punta Norte indicates that the size distribution of the burrowing clam population at that site is stable. In San Agustín, however, the mean size class distribution suggests a young population with recent recruitment.

In Punta Norte, older *Haliotis fulgens* individuals (with greater shell surface area) are infested with more boring clams per unit area than are younger abalone (with smaller shell surface area). The same pattern holds for *Haliotis corrugata* (Spearman correlation coefficient, Table 4).

Figure 8 shows the holes made by shell boring clams. Some clams remain in the holes and other epibionts, such as the boring sponge *Cliona* sp., make small holes in their shell. Only 81% of the infestation intensity obtained from direct count and extraction of the clams were revealed on X-ray plates, as boring clams on the edges of the abalone shell were not detected on the latter.

Figure 8. X-ray plate from *Haliotis fulgens*. Note the boring clams holes and boring clams inside (large arrow). Small dots indicate perforations produced by *Cliona* sp. or polychaetes (small arrow).

DISCUSSION

The differences in prevalence and density of infestation by boring clams between the abalone species from the same locality may be related to several factors, including age, shell area, abalone species, specific shell characteristics, vertical distribution of boring clams and particular environmental conditions. The total surface available for colonization by epibionts and the time spent underwater (age) by the substrate (abalone shell) are factors that determine the extent of colonization by benthic fauna. The depth distribution of the genus *Lithophaga* is similar to that of *Haliotis corrugata*, while *Penitella conradi* lives close to the lower intertidal zone where *Haliotis fulgens* is present (Soot-Ryen 1955, Keen & Coan 1974, Abbott & Haderlie 1980, Haderlie & Abbott 1980). A similar association was recorded in the red abalone *Haliotis rufescens* and black abalone *Haliotis cracherodii* in relation to the distribution of *P. conradi*, in California (Hansen 1970). The depth range of *H. rufescens*, which is primarily sublittoral, corresponds better to that of *P. conradi* than does that of the black abalone *H. cracherodii*.

The settlement of several mytilids, other bivalve species, and other invertebrates may be favored by filamentous and rugose substrates (Cáceres-Martínez et al. 1994). The rugosity of the yellow abalone's shell may thus present a better opportunity for settlement of mytilids and other invertebrates than the smoother shell of blue abalone. Shell chemistry may also influence boring clam settlement and penetration. Another consideration that could affect the density of epibionts on abalone shells is the differential growth rate of abalone from different localities. Some wild stocks of dwarf yellow abalone in Islas Benito have been recorded. These have a greater quantity of epibionts than those of normal growth (unpublished data).

Differences in boring clam prevalence and densities between the abalone from San Agustín and Punta Norte could be due to differential environmental conditions, since samples were taken on different dates (Punta Norte in November 1997, and San Agustin in June 1998). A direct comparison is thus difficult. Comparisons of growth rates and epibiont infestation between island abalone and mainland abalone in the area do not exist. The trend of more shell boring clams in older than in younger abalone, and in abalone with greater shell surface area than in those with smaller shell surface area must be investigated over a broad range of age and environment (mainland populations versus island populations).

To the best of our knowledge, this is the first record of the association of *Lithophaga aristata* and *L. plumula* with blue and yellow abalone. The genus *Lithophaga* has been widely recorded in association with corals (Scott 1986, Krumm & Jones 1993), submerged construction structures, sedimentary rocks (Kleeman 1994) and bivalves such as the pearl oyster (Doroudi 1996). *Penitella conradi* has been reported on shells of at least four abalone species on the Pacific coast, but most often in the red abalone (Haderlie & Abbott 1980).

Differences in the size distribution of burrowing clams from the studied localities indicate differences in recruitment and survival of these species. This may be associated with environmental conditions and collection dates. However, repeated monitoring of size class distribution is necessary to obtain information on the population dynamics of the burrowing clams. Moreover, it is necessary to investigate such environmental factors as currents, temperature and food availability to see if these are related to the presence and size class distribution of burrowing clams.

There are advantages and disadvantages to the two techniques used to determine the intensity of infestation by boring clams. The X-ray technique, although practical and non-destructive, does not allow identification of the boring clams and does not note the presence of all clams, missing those at the edges of the shell. On the other hand, extraction of the clams and direct counting is time consuming and shell destructive, although exact.

Economically, the results of this study highlight that it is possible for producers to detect certain zones that provide shells of different quality. It could thus enable managers to set regulations to protect abalone of these zones from the epibionts of other zones. For example, transplanting abalone from heavy burrowing clam-infested areas to those considered less infested could be controlled.

In conclusion, the yellow abalone had more boring clams, mainly of the genus *Lithophaga*, than the blue abalone. There is a trend of more boring clams in older and larger abalone (shell surface) than in younger and smallest abalone. More studies are needed to confirm the observed trend and to compare the density of boring clams between zones, and between mainland and island abalone populations. Additionally, studies investigating the possibility of managing different areas to obtain top quality abalone shells must be carried out.

ACKNOWLEDGMENTS

We thank Alejo Ojeda Ibarra from Pescadores Nacionales de Abulón for providing information about the abalone shell market, Ulises Núñez Míguez and Héctor Serrano Parra, for collaboration in shell processing. PARALYTIC SHELLFISH POISONING IN THE ABALONE *HALIOTIS MIDAE* ON THE WEST COAST OF SOUTH AFRICA

GRANT C. PITCHER,[1]* JOSE M. FRANCO,[2] GREGORY J. DOUCETTE,[3] CHRISTINE L. POWELL,[3] AND ANNA MOUTON[4]

[1]*Marine and Coastal Management, Private Bag X2, Rogge Bay, 8012, Cape Town, South Africa;* [2]*Instituto de Investigaciones Marinas, Eduardo Cabello, 6, 36208 Vigo, Spain;* [3]*Marine Biotoxins Program, Center for Coastal Environmental Health & Biomolecular Research, NOAA/National Ocean Service, 219 Fort Johnson Road, Charleston, SC 29412;* [4]*Arc-Onderstepoort Veterinary Institute, Private Bag X05, Onderstepoort 0110, South Africa*

ABSTRACT In April 1999, monitoring on two West Coast abalone farms provided evidence of the presence of Paralytic Shellfish Poisoning (PSP) toxins in the cultured abalone *Haliotis midae*. Subsequent analysis of wild animals collected from the West Coast also revealed the accumulation of PSP toxins in these gastropods. The toxicity of individual animals as measured by the AOAC mouse bioassay showed considerable variation, ranging from below the assay detection limit to a maximum of 1609 μg STXeq 100 g^{-1}. Initial observations found PSP toxins in abalone to be coincident with blooms of *Alexandrium catenella* indicating that this dinoflagellate was the probable cause of abalone toxicity. Subsequent detection by receptor binding assay, of toxicity in abalone on the South Coast, an area considered free of *A. catenella* blooms, casts some doubt as to the source of the toxins. The toxin composition in the abalone as determined by HPLC was dominated by STX, and differed significantly from the toxin profile of *A. catenella* and the co-occurring mussel, *Mytilus galloprovincialis*. Either these findings indicated a high capacity for biotransformation of PSP toxins by abalone or that *A. catenella* was not the source of the toxin. Investigation of the anatomical distribution of toxins revealed that they were not evenly distributed throughout the abalone tissues, but appeared to concentrate in outer layer tissue. The muscular foot made a disproportionately low contribution to the total toxin content of the mollusc, whereas the epipodial fringe, although comprising a small proportion of the abalone total weight, contributed substantially to the total toxin content. The epipodial fringe is typically included with the muscular foot as that part of the animal marketed for human consumption. The negative impacts of PSP contamination on abalone spawning and larval survival are presented and the findings of this study are compared to observations of PSP toxins in the abalone *Haliotis tuberculata* on the Galician coast. The inability of abalone to detoxify or depurate accumulated PSP toxins below the regulatory level threatens the future of the established abalone fishery and the newly developed aquaculture operations on the West Coast of South Africa.

KEY WORDS: Paralytic Shellfish Poisoning, saxitoxin, abalone, *Haliotis midae*, South Africa

INTRODUCTION

The abalone *Haliotis midae* forms one of the oldest fisheries on the South African coast, with present-day operations including recreational, subsistence, and commercial activities. During the 1990s, land-based farming of this species has also been under development and has recently attained commercial scale production. In April 1999, monitoring on two West Coast abalone farms provided evidence of the presence of Paralytic Shellfish Poisoning (PSP) toxins in cultured abalone. Subsequent analysis of wild animals also revealed the accumulation of PSP toxins in these gastropods.

The accumulation of PSP toxins typically occurs when toxic dinoflagellates are filtered from the water by bivalves such as clams, mussels, oysters, or scallops, which then accumulate the algal toxins to levels that are potentially lethal to humans or other consumers. Considerable progress has been achieved in the structural elucidation of PSP toxins. Following identification of the parent compound saxitoxin (STX), approximately two dozen naturally occurring derivatives have been described (Shimizu 1996), which vary greatly in their potency and are subject to interconversions and changes in relative proportions as they are transferred through the food chain. PSP occurs off the West Coast of South Africa and has always been attributed to the dinoflagellate *Alexandrium catenella* (Pitcher & Calder 2000), confirmed as the source of the toxin by Sapeika (1948). Although bivalve molluscs are the most common vectors of shellfish toxins, other vectors have been identified, including scavenging, predatory, and grazing gastropods (Shumway 1995). Abalone typically feed on kelp and other seaweeds. They are usually found attached to rocky substrates and feeding is accomplished by browsing on drifting seaweed. This feeding behavior and diet would indicate that abalone are unlikely candidates for the ingestion and accumulation of PSP toxins derived from toxic dinoflagellates such as *Alexandrium* spp., which primarily occur in the plankton.

This paper reports on investigations into the observations of PSP in abalone on the South African coast, including the incidence and distribution of toxic animals, the identification of the toxins, intrapopulation variation in toxicity, the anatomical distribution of toxins, and the depuration of toxins. The possible source and mode of uptake of toxins and the potential impact on spawning and recruitment success are also considered.

MATERIALS AND METHODS

Animals analyzed for this study were collected from five abalone farms, (Farms A–E) and from the field, at sites spread between the northern and southern farm locations (Fig. 1). All data presented here originate from animals collected between April 1999 and December 1999. A single wild animal collected in the vicinity of Jacobsbaai in April 1998 was also analyzed. The AOAC mouse bioassay was used in the routine analysis of PSP toxicity and a receptor-binding assay was utilized for comparative purposes. High performance liquid chromatography and mass spectrometry were used to determine and confirm, respectively, the

toxin composition in abalone. The toxin composition of the PSP-producing dinoflagellate, *A. catenella*, and the mussel, *Mytilus galloprovincialis*, collected at Elands Bay during March 1999 were also determined for comparative purposes.

Intrapopulation variability in toxicity was investigated by analysis of individual animals of the same size cultured under similar conditions or collected from the same locality in the wild. In most instances, the entire animal, once removed from the shell, was used in the analysis. In other cases, toxin analysis was carried out on specific body parts (e.g., the viscera, foot, epipodial fringe, digestive gland, gonad, mantle, or gills) to examine the anatomical distribution of toxins. Foot and epipodial fringe tissues were also analyzed following removal of epithelial tissue by scrubbing. Typically, analyses were performed on individual abalone, but in some cases, animals were pooled for analysis.

In assessing the rate of toxin depuration, 60 cultured animals were removed from Farm B on 13 May 1999 and 60 wild animals were removed from Paternoster on 29 June 1999, and placed under controlled conditions in a Cape Town laboratory. The animals were maintained on a diet of kelp in flow-through tanks supplied with filtered (18 μm) seawater. Abalone were periodically sacrificed to assess the rate of depuration. The mouse bioassay was used to measure toxicity and two animals were sacrificed for each assay in order to reduce the effects of intrapopulation variability in toxicity.

In an attempt to ascertain the source of the toxins, time-series data on the incidence of the PSP-producing dinoflagellate, *A. catenella*, at Elands Bay on the West Coast are presented. Data on the distribution of PSP toxin-contaminated bivalves, as monitored during the period 1989–1999 are also presented. These data were collected as part of a Harmful Algal Bloom monitoring program detailed by Pitcher and Calder (2000). The distribution of toxic shellfish is compared to the distribution of abalone catches, determined by the Total Allowable Catch allocations, which generally reflect the distribution of abalone (R. Tarr pers. comm).

When PSP contamination of cultured abalone was initially detected, problems with spawning and larval survival were experienced on affected West Coast farms. Samples of eggs and larvae from these farms were examined by light and scanning electron microscopy and compared to normal eggs and larvae of the same age from a farm on the South Coast. Samples of eggs were collected at spawning, at fertilization, and at regular intervals until hatching. Samples of larvae were collected at regular intervals from hatching until settlement. All samples were taken in duplicate, one sample placed in 4% gluteraldehyde in 0.2 M sodium cacodylate buffer and the other in Davidson's fixative (Austin and Austin 1989). Animals fixed in gluteraldehyde were processed for scanning electron microscopy. Samples were rinsed twice in sodium cacodylate buffer, after which they were dehydrated through an ascending series of ethanol. The samples were then critical point dried from 100% ethanol through liquid carbon dioxide in a Polaron Critical Point Drier. Dried samples were mounted onto viewing stubs and sputter coated with gold. Samples were viewed at 3 to 8 kV accelerating voltage in a Hitachi S-2500 Scanning

Electron Microscope. Animals fixed in either gluteraldehyde or Davidson's fixative were processed for light microscopy. Samples were rinsed twice in distilled water to remove adhering detritus. A modified double embedding technique (Austin & Austin 1989) was used prior to processing routinely for light microscopy. Sections were cut at 6 μm thickness and stained with haematoxylin and eosin.

The following procedures were adhered to in the analysis of PSP toxins:

Mouse Bioassay

Net toxicity was measured by the standard AOAC mouse bioassay (Association of Official Analytical Chemists, AOAC 1990), the method adopted worldwide to monitor the safety of shellfish PSP toxin levels for human consumption. Acidic aqueous extraction of the tissue in 0.1 M hydrochloric acid (heated to 100° C) was followed by intraperitoneal injection of 1 ml of the extract into each of three standardized mice. The time from initial injection to mouse death was recorded and the toxicity determined from Sommer's table.

HPLC-FD

High performance liquid chromatography with fluorescence detection (HPLC-FD) was used to determine the concentration of individual PSP toxins (Franco & Fernández -Vila 1993). The separation of toxins was carried out in a 5 μm Lichrospher 100 RP-18 column (125 × 4 mm i.d.). Two isocratic elutions were used, the first, for the separation of the carbamate toxins, neoSTX, dcSTX and STX, and the second for the separation of the GTX toxins. The first eluent was 1.5 mM octane sulfonate in 10 mM ammonium phosphate buffer (pH 7.2) plus 6% acetonitrile, at a rate of flow of 1 mL min^{-1}. The second eluent was 2 mM octane sulfonate in 10 mM ammonium phosphate buffer (pH 7), at a rate of flow of 0.8 mL min^{-1}. The detector was a Waters 474 spectrofluorimeter, set at 330 nm ex., 390 nm em. Millennium software was used for recording and integrating peaks. Two pumps were used for delivering postcolumn reagents. The postcolumn reaction was performed in a Teflon coil (10 m × 0.5 mm i.d) at 65° C. The first reagent was the oxidant, a solution of 7 mM periodic acid in 50 mM sodium phosphate (pH 9), and the second the acidifiant, a 0.5 M solution of acetic acid. Both were delivered at a rate of flow of 0.4 mL min^{-1}. The toxin reference standards for dcSTX and STX were supplied by the project EUR 18318 of the European Commission. The remaining reference standards for neoSTX and GTX_{1-4} were purchased from the National Research Council of Canada. The C_s, GTX_5 and GTX_6 toxins were identified and quantified by mild acid hydrolysis of the sample with an equal volume of 0.4 M HCl at 100°C for 15 min. This process transforms C_1 to GTX_2, C_2 to GTX_3, C_3 to GTX_1, C_4 to GTX_4, GTX_5 to STX and GTX_6 to neoSTX. The values of toxicity were expressed in μg STX eq 100 g^{-1} tissue thereby enabling comparison of HPLC and mouse bioassays. Values in μg toxin g^{-1} were derived from the sum of the concentrations of all toxins detected by HPLC. These values were converted to μg STX eq 100 g^{-1} by means of molar specific conversion factors inferred from the values of specific toxicity given by Oshima (1995).

Confirmation of the presence of STX was performed by mass spectrometry with an ion-trap mass spectrometer model LCQ (Finnigan, ThermoQuest, USA). Off-line "nanospray" ionization was carried out using disposable gold-coated capillary probes, as described previously by Marina et al. (1999). The specific detection of toxins at high sensitivities was performed by examining for the appearance of daughter ions produced by the fragmentation of the corresponding precursor ions.

Receptor Binding Assay

The receptor binding assay used in the detection of PSP toxins exploits the highly specific interaction of these compounds with their biological receptor, the voltage-dependent sodium channel, and is therefore based on functional activity (Doucette et al. 1997, Powell & Doucette [In Press]). This assay has been compared with mouse bioassay-based toxicities of AOAC extracts of various bivalve molluscs and results between methods agreed closely (Doucette et al. 1997). The assay protocol and calculations of sample values used herein follow those described by Doucette et al. (1997) and modified by Powell and Doucette (In Press). Briefly, the receptor assay was performed in a microplate filtration format and involved the incubation of a rat brain synaptosome preparation containing the receptors, with [^{3}H]-STX and unlabeled PSP toxins contained in a standard or sample. After removal of unbound toxin by washing, the remaining bound radioactivity (i.e., [^{3}H]-STX), which is inversely and quantitatively related to the concentration of PSP toxins in a sample, was determined by scintillation counting on a Wallac MicroBeta model 1450. Toxin concentrations were expressed in terms of μg STX eq 100 g^{-1}.

RESULTS AND DISCUSSION

Incidence and Distribution of Toxic Abalone

In April 1999 monitoring of abalone at Farm B, for PSP toxins by means of the mouse bioassay, yielded positive results. Subsequent tests at the nearby Farm A were also positive and many of these animals were reported to be paralyzed, in that they were no longer able to attach to a substrate and were unable to right themselves. Brood stock were amongst the animals affected and some mortalities were recorded. At this time, divers reported the presence of a large number of detached or paralyzed abalone in the kelp beds in the vicinity of Paternoster and analysis of these animals also indicated the presence of PSP toxins. Subsequent to these initial findings, approximately 300 abalone, both cultured and wild, from five abalone farms and from several sites in the field have been analyzed by mouse bioassay. Although toxin concentrations varied considerably at each locality, the highest toxin concentrations were recorded on the northernmost farm, Farm A, where the single highest value was 1609 μg STX eq 100 g^{-1}. Toxin concentrations generally decreased southwards and the Cape Peninsula was the southern limit of toxic abalone as detected by the mouse bioassay (Fig. 1).

On the two West Coast farms toxin concentrations exceeded the regulatory level of 80 μg STX eq 100 g^{-1} in the majority of animals, particularly on Farm A (Fig. 2a, b). Although toxins were detected in nearly all the wild animals tested on the West Coast, toxin concentrations were less than the regulatory limit in the majority of these animals (Fig. 2c). Of all the abalone tested on the South Coast by mouse bioassay, toxicity was detected only in animals collected on the western shores of False Bay (Fig. 2d). However, analysis of abalone from Farms C, D and E by means of the more sensitive receptor binding assay revealed the presence of PSP toxins at concentrations below those detectable by the mouse bioassay (Fig. 1b). Assessment of all toxin analyses indicated a

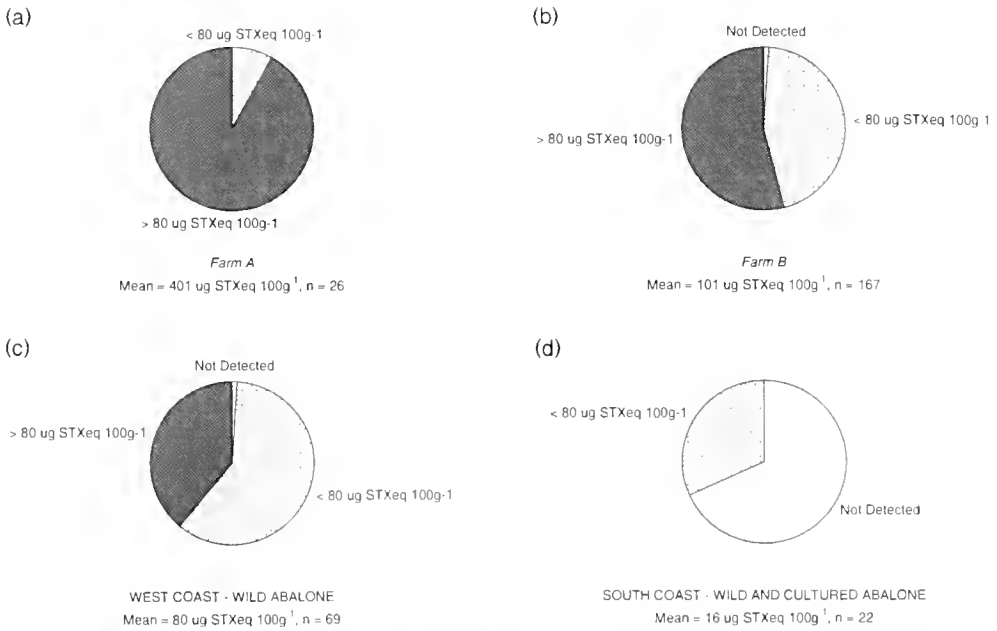

Figure 2. The incidence of toxic abalone as detected by the mouse bioassay on (a) *Farm A* (b) *Farm B* (c) from wild animals collected on the West Coast, and (d) from both cultured and wild animals collected on the South Coast.

geographical gradient in abalone toxicity, toxin concentrations decreasing from north to south.

Analysis of a single wild abalone from Jacobsbaai collected in April 1998 by means of the mouse bioassay provided a negative result. Although not conclusive, this single sample suggests that PSP toxins were not present in abalone, at concentrations detectable by the mouse bioassay, during the previous year.

Toxin Composition

As the mouse bioassay is a non-specific test and owing to the fact that abalone are unlikely candidates for the accumulation of PSP toxins, analysis by means of HPLC and mass spectrometry was required to identify and confirm the presence of PSP toxins. The toxin composition of abalone as determined by HPLC was rather unusual in that it was dominated by a single toxin, notably STX (Fig. 3a). The presence of STX was confirmed by mass spectrometry by the appearance of daughter ions (282 DA) produced by the fragmentation of the corresponding precursor ions (300 DA).

The specific toxicity and toxin composition of the PSP-producing dinoflagellate, *Alexandrium catenella*, present in bloom proportions in Elands Bay during March 1999, were also investigated. Different dinoflagellate strains vary greatly in their specific toxicity depending on environmental and growth conditions, and the single measurement of 1.75 pg STX eq $cell^{-1}$ classify this dinoflagellate as a strain of low toxicity. The relative proportion of various PSP derivatives is a conservative property for a given isolate (Cembella et al. 1987) and the blooms in Elands Bay were found to be characterized by a high proportion of the less toxic N-sulfocarbamoyl toxins (C_1 and C_2) and moderate proportions of the more potent carbamate (STX and GTX_4) and decarbamoyl toxins ($deGTX_3$) (Fig. 3b).

Simultaneous collection and analysis of the mussel, *Mytilus galloprovincialis*, from Elands Bay during March 1999 provided toxicity values of 1 610 and 60 940 μg STX eq 100 g^{-1} as determined by the mouse bioassay and HPLC, respectively. A significant difference between the toxin profile of the causative dinoflagellate and the contaminated bivalve indicated a high degree of toxin transformation (Fig. 3c). It is well known that the toxin composition in bivalve tissues can differ significantly from that of the toxic dinoflagellates ingested (Bricelj & Shumway 1998) and as is often the case with bivalves, the mussels were found to contain reduced proportions of N-sulfocarbamoyl toxins (C_1 and C_2) and higher proportions of the carbamate toxins (neoSTX and STX). This observation is common when the algae ingested are rich in N-sulfocarbamoyl toxins which are more labile than other toxins and therefore more likely to be transformed to their more toxic carbamate analogs (Hall & Reichardt 1984). Although the precise in vivo mechanism of conversion between N-sulfocarbamoyl and carbamate toxins in shellfish has not been determined, it may lead to an increase in net toxicity (Bricelj & Shumway 1998). The dramatically different toxin profile of *H. midae* compared to *A. catenella*, indicates either a very high capacity for biotransformation of PSP toxins by abalone or that *A. catenella* was not the source of the toxin.

Toxicity as measured by HPLC was notably higher than that measured by the mouse bioassay where y and x are toxicity measured by HPLC and mouse bioassay respectively,

$$y = 2.34x + 340.7,\ F = 12.1,\ r^2 = 0.57,\ p < 0.007$$

Intrapopulation Variation in Toxicity

Toxicity as measured by the mouse bioassay showed considerable variation between individual animals, exceeding that accounted for by imprecision in the mouse bioassay (ca. +/– 20%, Adams & Furfari 1984). For example, on Farm A, the measured values of toxicity for whole animals ranged from 63–1609 μg STX eq 100 g^{-1}. An understanding of the causes of this high intrapopulation variation in toxicity is crucial in the design of monitoring programs for the assurance of seafood safety (Bricelj & Shumway 1998).

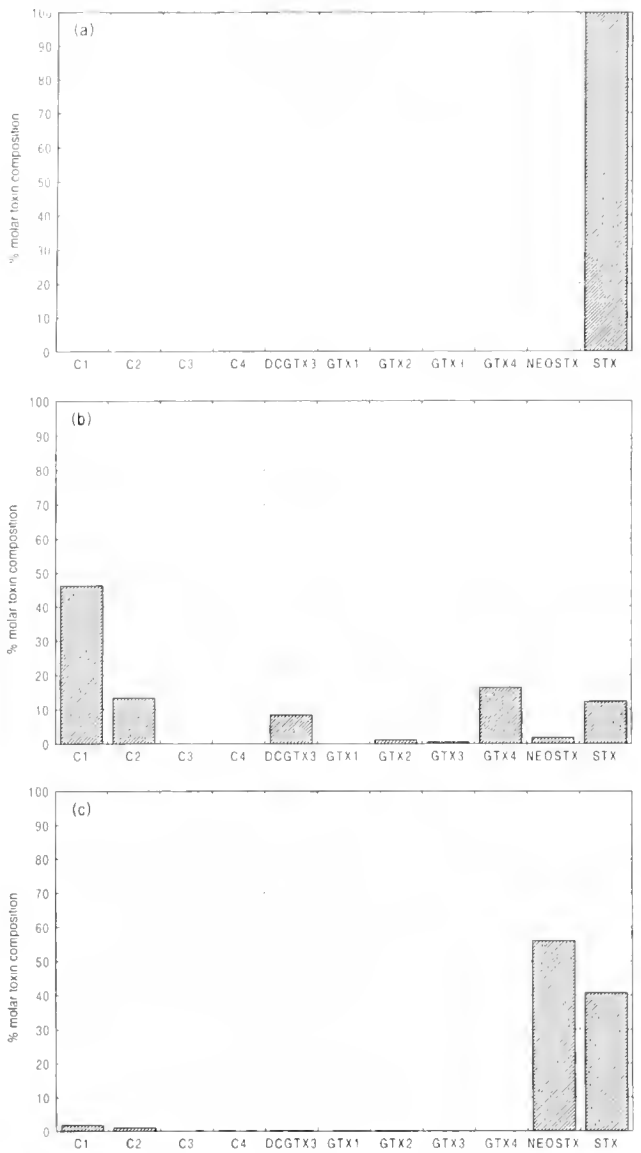

Figure 3. Toxin composition of (a) cultured and wild abalone *Haliotis midae*, (b) a phytoplankton sample with a high proportion of cells of *Alexandrium catenella* and (c) the bivalve *Mytilus galloprovincialis* (the phytoplankton and bivalve samples were collected during March in the vicinity of Elands Bay).

In this study, animals of a similar size and subjected to similar conditions of exposure to PSP toxins, such as farmed animals from a single basket or wild animals from a particular region, demonstrated marked variability in toxicity (Fig. 4). The toxicity of 10 animals (size: 55–60 mm) sampled from a single basket on Farm B, ranged more than 5-fold from 57–307 μg STX eq 100 g^{-1}. Similarly, the toxicity of 10 animals (size: all 30 mm) sampled from a single basket on Farm A, also ranged 5-fold from 77–383 μg STX eq 100 g^{-1}. The toxicity of 52 animals collected in the vicinity of Robben Island (size: 115–170 mm) ranged more than 10-fold from 29–314 μg STX eq 100 g^{-1}. This variability prevented the identification of any trends in toxicity associated with individual differences, such as body size, which are considered to influence toxin accumulation rates.

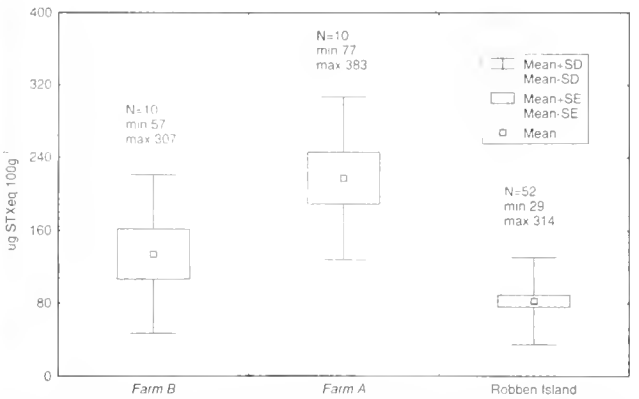

Figure 4. Intrapopulation variability in toxicity in abalone tested from a single basket at each of *Farms A* and *B*, and from abalone harvested in the vicinity of Robben Island.

Anatomical Distribution of Toxins

Paralytic shellfish toxins are not evenly distributed throughout shellfish tissues, resulting in pronounced differences in the absolute toxicities of individual tissues. The contribution of each tissue to the total toxin body burden is therefore a function of both its absolute toxicity and relative weight contribution.

Discarding of those tissues that selectively sequester PSP toxins (e.g. evisceration) may, in some cases, provide an effective tool to reduce the risk of PSP (Bricelj & Shumway 1998). In many instances only the foot of the abalone is marketed for human consumption, therefore the anatomical distribution of toxins is of considerable interest and importance. This study has revealed that toxins are not evenly distributed throughout the tissues of abalone (Fig. 5). Initial investigations divided the animals into three components, the viscera, foot, and epipodial fringe. Results indicated moderate toxicity in both the viscera and foot with dramatically higher levels of toxin in the epipodial fringe, a body component with a high surface area. Therefore, the muscular foot of abalone, despite contributing substantially to the total weight of the abalone, makes a disproportionately low contribution to the total toxin content of the animal. The epipodial fringe, while making only a small contribution to the total weight of the abalone, contributes substantially to the total toxin content and is typically included with the muscular foot in that part of the animal marketed for human consumption. The removal of epithelial tissue by scrubbing both the foot and epipodial fringe dramatically lowered the toxin levels in these tissues, suggesting that the toxins were concentrated in the epithelium (Fig. 5a). Scrubbing could therefore provide a possible means of reducing the levels of toxin prior to marketing the product for consumption.

Further studies included examination of gill, mantle, digestive gland, and gonad tissue (Fig. 5b). These results varied somewhat from the initial investigations. Very high toxin levels were evident in the gill tissue, again indicating the accumulation of toxins in outer layer tissue. The toxicity of the digestive gland was also particularly high. Although toxin levels in the epipodial fringe were substantially less than those measured in the initial experiments, they were significantly higher than those in the foot and gonad. The capacity for in vivo biotransformation and the selective retention of individual PSP toxins, are major determinants of the differences in toxicity among tissues. However, establishment of

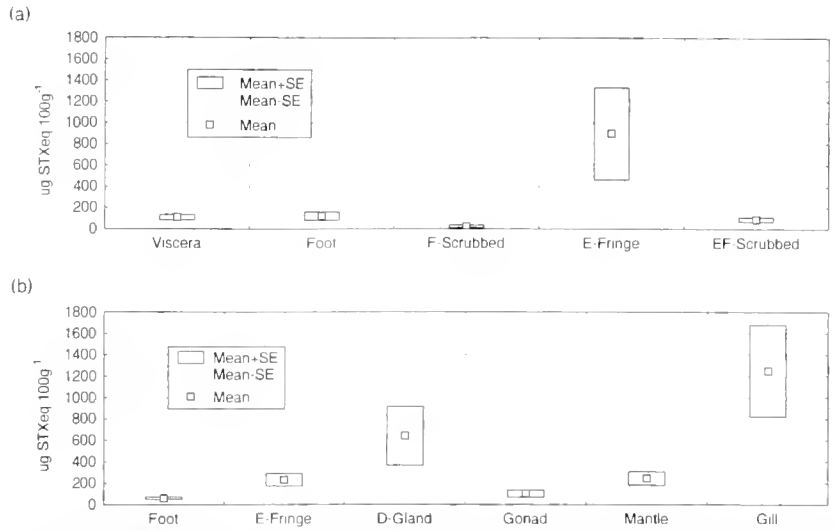

Figure 5. Anatomical distribution of toxins as determined in (a) the viscera, foot, and epipodial fringe (toxin concentrations were also determined following removal of epithelial tissue from the foot and epipodial fringe by scrubbing (n = 12)) and (b) the foot, epipodial fringe, digestive gland, gonad, mantle, and gill tissue (n = 10).

the source and mode of uptake of the toxins in abalone is required to understand the distribution of toxins and how they may change over time.

Depuration of Toxins

In order to manage the problem of PSP in abalone it is important to establish the rate of depuration of toxins, as shellfish are known to vary markedly in their ability to detoxify accumulated toxins. Cultured and wild abalone were placed under controlled aquarium conditions and periodically sacrificed and analyzed for toxins in order to assess the rate of detoxification (Fig. 6). The results obtained over a 7-month period indicate that the prolonged retention of toxins is a characteristic of abalone. During this period, measures of toxicity ranged from below the regulatory level to 853 μg STX eq 100 g^{-1} with no apparent declining trend, thus reflecting only the high intrapopulation variation in measured toxin levels.

Incidence of Alexandrium catenella *and PSP*

The only known source of PSP toxins in the Benguela is the dinoflagellate, *A. catenella*, which is usually associated with red tide on the West Coast of South Africa (Pitcher & Calder 2000). A seven year time-series obtained from daily monitoring at Elands Bay provides an indication of the interannual variability in the incidence of *A. catenella* in the plankton on the West Coast (Fig. 7). Although *A. catenella* is typically observed each year as a component of the plankton, usually in the latter months of summer, the detection of PSP toxins in abalone for the first time appears to have coincided with particularly high concentrations of *A. catenella*. Furthermore, at the time at which toxins were first detected in abalone on Farm B, examination of water samples from the farm revealed an abundance of *A. catenella*.

Blooms of this dinoflagellate are common north of Cape Columbine and are usually advected southwards, often as a flood event, during late summer and autumn. Blooms typically do not extend beyond Cape Point onto the South Coast (Pitcher & Calder 2000). Consequently the highest incidence of PSP is observed north of Cape Columbine while PSP has not been recorded east of Cape Point (Fig. 8a). Initial observations of PSP toxins in abalone therefore coincided temporally and spatially with blooms of *A. catenella*, indicating that this dinoflagellate was the probable cause of abalone toxicity. Subsequent detection, however, of low concentrations of PSP toxins in abalone on Farms C, D and E, on the

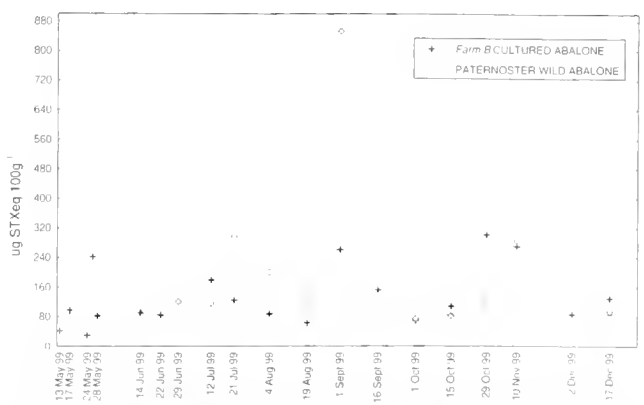

Figure 6. A time series of toxin concentrations in abalone removed from *Farm B* and from the wild at Paternoster and maintained under controlled laboratory conditions.

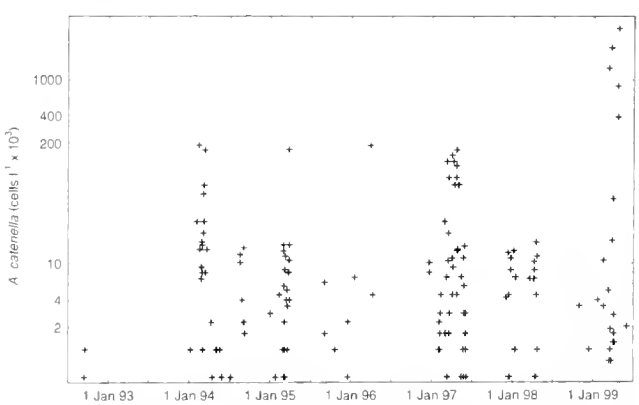

Figure 7. Daily time series of *Alexandrium catenella* concentrations at Elands Bay for the period 1 July 1993 – 30 June 1999.

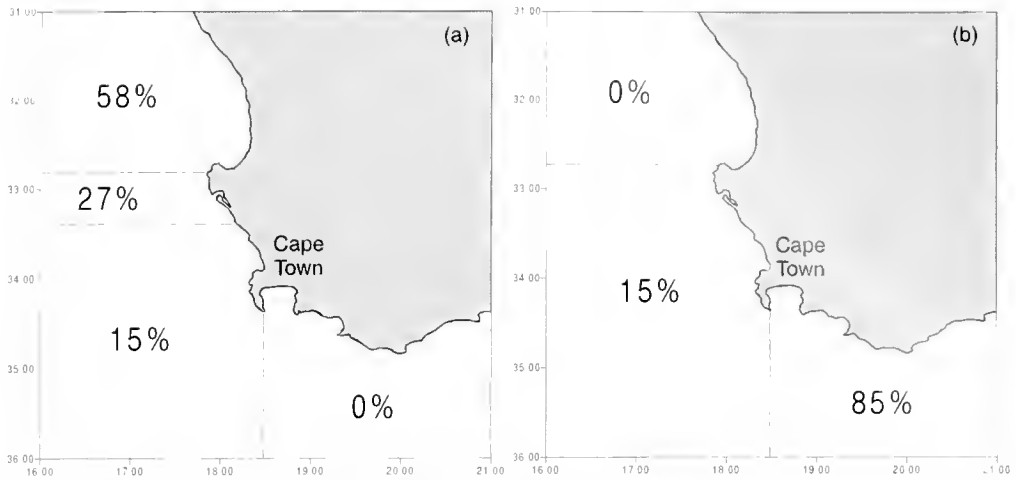

Figure 8. (a) The incidence of PSP-contaminated mussels, *Mytilus galloprovincialis*, as monitored during the period 1989–1999 (as % of the total samples in which PSP toxins were detected by means of the mouse bioassay) and (b) the distribution of abalone catches.

South Coast, an area considered to be free of blooms of *A. catenella*, casts some doubt as to the source of PSP toxins in abalone at least in this region.

Potential Ecological Impact

The contamination of bivalves is usually facilitated by their relative insensitivity to PSP toxins. However, it has become apparent that harmful algae may compromise survival and growth in some bivalve populations (Shumway 1990), although little is known about the ecological effects PSP toxins may have on field populations. Results of this study indicate that within the abalone fishery, recruitment may be severely influenced by PSP.

The contamination of abalone with high levels of PSP toxins on Farm A was accompanied by clinical signs of paralysis in certain animals, including brood stock. Animals dropped off the sides of holding tanks and were unable to right themselves, and some mortalities were experienced. Histological examination of affected animals showed no significant abnormalities. Brood stock that recovered resumed spawning, but viable larvae were not produced. Light and scanning electron microscopy of eggs and larvae from Farm A showed irregular division of eggs and the formation of grossly abnormal larvae (Fig. 9). The larvae were characterized by irregular shapes and the appearance of cilia in clumps over their entire surface. Although most eggs containing such larvae hatched, the larvae were unable to swim and did not develop further. Problems with larval development persisted for several months. It is not possible to say whether the larval abnormalities were directly related to PSP contamination. It is likely that the reproductive problems were caused by the deterioration in brood stock health and that the effect of the toxin on larval development is therefore only indirect. Similar, larval abnormalities could probably be caused by other brood stock stressors, but further research is needed to investigate this possibility.

In comparing the distribution of PSP toxin-contaminated mussels (Fig. 8a) to the distribution of abalone catches (R. Tarr, pers. comm) which generally reflect the distribution of abalone (Fig. 8b), we find them to be inversely distributed. That is, abalone are absent from areas where there is a high incidence of PSP, but abundant in areas not prone to PSP. Without any obvious physiological or ecological factors determining the northern limit to the distribution of abalone, these results suggest that the absence of abalone north of Columbine may be determined by the higher incidence of PSP toxins in that region.

A Comparison to the Observations of PSP Toxins in Haliotis tuberculata *on the Galician Coast*

The only other occurrence of PSP toxins in abalone has been reported in the species *Haliotis tuberculata* on the Galician coast of Spain. In 1991 Martinez et al. (1993) detected PSP toxicity in samples of abalone collected in the Ria de Arousa, and the Galician Coast was closed to the harvesting of abalone in 1993 as toxin levels exceeded the regulatory limit (Bravo et al. 1996). A number of comparisons may be made between the observations of PSP toxins in abalone on the Galician and South African coasts. The single greatest difference was in the toxin composition profile Fig. 10). Whereas *H. midae* was dominated by STX, *H. tuberculata* was dominated by decarbamoylsaxitoxin (dcSTX) with a small proportion of STX (Nagashima et al. 1995, Bravo et al. 1999). Similarities included the observation of highest toxicity in the epithelium of the *H. tuberculata* foot (Bravo et al. 1999), with the absolute toxicity of the epithelium being more than 300-fold greater than that of the gut or muscle. Another similarity was the slow depuration of toxins, as Bravo et al. (1996) observed no depuration of toxins in *H. tuberculata* maintained under controlled laboratory conditions for 3 mo.

As is the case in *H. midae*, the source or origin of toxins in *H. tuberculata* remains uncertain, as the geographical range of the toxic abalone does not coincide exactly with the PSP-producing dinoflagellates known in the region. On the Galician Coast, no significant differences have been observed in the toxicity of abalone from different locations, despite a higher incidence of toxic dinoflagellates on the central and southern coasts. Since abalone attach to rocky substrates and browse on kelp and other seaweeds, the toxins may originate from these seaweeds. Other potential sources may include bacteria and bluegreen algae. If toxic dinoflagellates are the source of toxins in abalone, the mode of

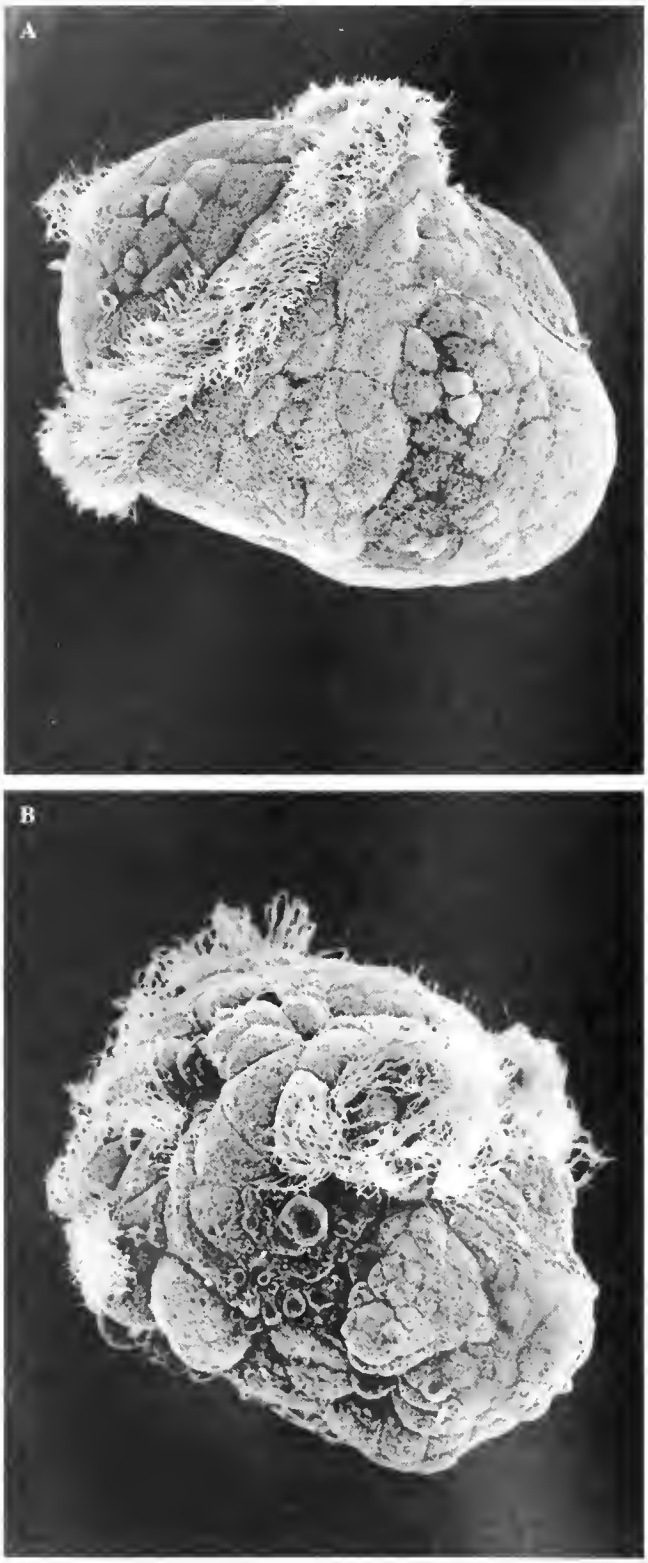

Figure 9. (a) A normal newly hatched larva known as a trochophore stage and (b) an abalone larva produced by PSP-contaminated broodstock. The normal larva is able to swim and remains planktonic for approximately five days. It is regular in shape, possesses a clearly defined protostomal tuft and a continuous and complete velum.

uptake remains to be determined. It is possible that settled vegetative cells or cysts may be taken up during feeding and observations in culture have indicated a high incidence of *A. catenella* cells associated with the mucilage layer of kelp fronds. The production of extracellular toxins by *A. catenella* may also serve as a possible source of PSP toxins and the adsorption/uptake of these toxins by abalone may provide an explanation for the accumulation of toxins in outer layer tissue.

The observations of PSP toxins in abalone also show several similarities to those made on the butter clam *Saxidomas giganteus*. Toxins were, as in *H. midae*, preferentially accumulated as STX in the outer surface of the siphons. STX was accumulated in clams feeding on an *Alexandrium* isolate containing GTX and neoSTX but no STX, and STX accumulated in the siphon only after the depuration of GTX and neoSTX (Beitler & Liston 1990). Although immunohistochemical studies showed the location of STX to be in the columnar epithelium (Smolowitz & Doucette 1995), the mechanism of tissue-specific retention of PSP toxins remains to be elucidated. Long-term retention, of high levels of STX has also been reported, typically taking several months to years to detoxify below the regulatory limit (Quayle 1969, Beitler & Liston 1990). Price and Lee (1971), and Price and Lee (1972) suggested that pH-dependent binding of STX to the melanin-containing tissues of the siphon was a mechanism of toxin retention in this species and Kvitek (1991), and Kvitek (1993) speculated that toxin compartmentalization in butter clams had evolved as a chemical defense mechanism to reduce predation on clams. A similar mechanism of STX retention may exist in abalone which also possess melanin-containing tissue (Fox 1983). However, recent investigations by Bravo et al. (Submitted) have indicated that the toxins are associated with secretory cells of the epithelium and not with cells containing granules of melanin-like pigment.

CONCLUSION

The findings of this study support the need for the inclusion of non-filter feeding molluscs in routine monitoring programs. The presence of PSP toxins in abalone now threatens the future of the abalone fishery and the newly developed aquaculture operations on the West Coast of South Africa. This threat is made more ominous by the slow depuration of toxins to below the regulatory level and by our limited understanding of the causes of the problem. Priority areas of research should therefore focus on identification of the origin and establishment of the mode of uptake of the toxins. The concentration of toxins in the epithelium may provide the possibility for the development of a fairly simple treatment to reduce the toxicity to below the regulatory limit in the marketable product. Management of the problem of PSP toxins in abalone by such means needs to be explored further.

ACKNOWLEDGMENTS

We thank Cecilia Viljoen, Karen Whyte, Nick Loubser, Andre du Plessis and Paul Williams for supplying numerous abalone samples, and Desiree Calder for preparing these samples for toxin analysis. Components of the research were supported by the project MAR 95-1849.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

—Sponsors an annual scientific conference.
—Publishes the peer-reviewed *Journal of Shellfish Research.*
—Produces a Quarterly Newsletter.
—Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

—You will meet kindred scientists, managers and industry officials at annual meetings.
—You will get peer review through presentation of papers at the annual meeting.
—If you are young, you will benefit from the experience of your elders.
—If you are an elder, you will be rejuvenated by the fresh ideas of youth.
—If you are a student, you will make useful contacts for your job search.
—If you are a potential employer, you will meet promising young people.
—You will receive a scientific journal containing important research articles.
—You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

—Fill out and mail a copy of the application blank below. The dues are 65 US $ per year ($35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: _____ For the calendar year: ____ Date: _____
Mailing address: _____
_____
_____
Institutional affiliation, if any: _____
Shellfishery interests: _____

Regular or student membership: _____
Student members only—advisor's signature REQUIRED: _____

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for $65 ($35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").
- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots:* 1000 dpi; *halftones/grayscales:* 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

FIELD IDENTIFICATION OF THE EUROPEAN GREEN CRAB SPECIES: *CARCINUS MAENAS* AND *CARCINUS AESTUARII*

SYLVIA BEHRENS YAMADA AND LAURA HAUCK
Zoology Department, Oregon State University, Corvallis, Oregon

ABSTRACT Adults of the global invaders, *Carcinus maenas* and *C. aestuarii*, can generally be distinguished in the field by three diagnostic characteristics: the shape of the copulatory appendages (pleopods) in the male, the shape of the frontal area between the eyes, and the carapace width to length ratio. The pleopods of male *C. maenas* are crescent-shaped and curve outward with the center of the crescents touching; those of *C. aestuarii* are straight and parallel to one another. The frontal area of *C. maenas* does not protrude and is bordered by three scalloped-shaped lobes with distinct bumps. The frontal area of *C. aestuarii* is flat without distinct bumps and protrudes beyond the eyes. The carapace width to length ratio of adult crabs is typically >1.29 for *C. maenas* and <1.27 for *C. aestuarii*.

KEY WORDS: *Carcinus maenas*, *Carcinus aestuarii*, sibling species, invasive species, green crab

INTRODUCTION

The European green crab, a native to Europe and North Africa, is receiving much attention lately because of its success as a global invader. Established breeding populations outside its native range are currently found in Japan, South Africa, Australia, Tasmania, and on both the east and west coasts of North America (Le Roux et al. 1990, Cohen et al. 1995, Grosholz & Ruiz 1995, Furota et al. 1999).

Two forms of the green crab are now recognized: the Atlantic *Carcinus maenas* (Linnaeus, 1758) and the Mediterranean *C. aestuarii*, Nardo, 1847 (old name *Carcinus mediterraneus* Czerniavsky, 1884) (Demeusy & Veillet 1953, Demeusy 1958, Holthuis & Gottlieb 1958, Almaça 1961, Zariquiey Alvarez 1968, Bulheim & Bahns 1996, Geller et al. 1997). The Strait of Gibraltar, with its high sill, acts as a partial barrier to larval and gene exchange. Consequently, Mediterranean populations of many marine organisms, including the green crab, diverged from their Atlantic counterparts (Demeusy & Veillet 1953, Barsotti & Meluzzi 1968, Almaça 1989, Quesada et al.1995, Saavedra et al. 1995, Bulnheim & Bahns 1996, d'Udekem d'Acoz 1999). There is evidence, however, of some mixing of *Carcinus* populations near the Strait of Gibraltar (Almaça 1961, Clark et al. 2001, Armand Kuris, unpubl. observations).

Within the last two centuries, *Carcinus* has been accidentally introduced into several regions outside its native range as a result of maritime commerce and ballast transport: *C. maenas* to the east and west coast of North America, Australia, Tasmania, and South Africa; and *C. aestuarii* to Japan (Almaça 1962, Geller et al. 1997). Since *Carcinus* spp. tolerate air exposure, starvation, and wide ranges in temperature and salinity, they are well adapted to survive ocean voyages and plane rides. Furthermore, the free-swimming larvae have the potential to survive within the ballast tanks of cargo ships. Once released into a new environment, these ecological generalists can subsist on a variety of food organisms, including marsh vegetation, algae, crustaceans, mollusks, and fish (Cohen et al. 1995). Under favorable conditions, both species can reach sexual maturity within 1 y (Grosholz & Ruiz 1995, Furota et al. 1999, Behrens Yamada & Hunt 2000). The planktonic larvae produced by colonists can travel on ocean currents and "seed" new breeding populations elsewhere (Behrens Yamada & Hunt 2000). Marine scientists, resource managers, shellfish growers, and members of the general public are concerned that these invaders may adversely affect marine communities by altering food webs, disturbing habitats, displacing native species, and preying on commercially important clams, mussels, oysters, and juvenile native crabs.

When a green crab is sighted in a new geographical area, it is important to rapidly confirm its identity, its source, and its mode of introduction. Once a vector has been identified, steps can be taken to prevent further individuals from arriving. If the numbers of a new invader can be kept below a critical threshold, a self-perpetuating population may not establish itself. Time is thus paramount in identifying the invader's origin. While it may be possible to identify the most likely source of a new green crab invader with genetic tools (Bulnheim & Bahns 1996, Geller et al. 1997, Bagley & Geller 2000), these procedures take time and resources to implement. We propose that a fast, simple field identification method be used to identify which *Carcinus* species is actually invading.

Green crabs can be distinguished from other crabs in Europe and North America by their fan-like shaped carapace, five prominent, sharp anterio-lateral teeth behind the eyes, and three lobes between the eye sockets (Fig. 1; Crothers & Crothers 1988). Distinguishing the Atlantic from the Mediterranean species, however, takes closer inspection. Various studies have focused on green crab species identification, but these references are not readily available to most English-speaking scientists and resource managers because they are dated and/or published in Spanish, French, and Portuguese journals. Our goals are to list all the distinguishing characteristics described in the literature and to evaluate the usefulness of each in a field setting. The latter was accomplished by examining preserved museum specimens from collection sites in the Mediterranean and Atlantic and fresh specimens from Oregon.

MATERIALS AND METHODS

We compiled the literature on green crab species identification and created a list of characters that could potentially be useful for distinguishing *C. maenas* and *C. aestuarii* (Table 1). In addition, Dr. Toshio Furota kindly sent us his unpublished observations on the physical characteristics of *C. aestuarii* from Shinhama lagoon in Tokyo Bay Japan.

In order to evaluate the usefulness of each morphological feature in field identification, we obtained preserved specimens of similar size male *C. maenas* and *C. aestuarii* from the Smithsonian Museum of Natural History. Collection sites included Vlissingen, Netherlands, Chausey Islands in the English Channel, Rabat, Morocco, Tunis, Tunisia, and Marsala, Sicily (Fig. 2; Table 2). To supplement these samples, we collected live specimens from Yaquina Bay, Oregon using baited and pitfall traps. For each

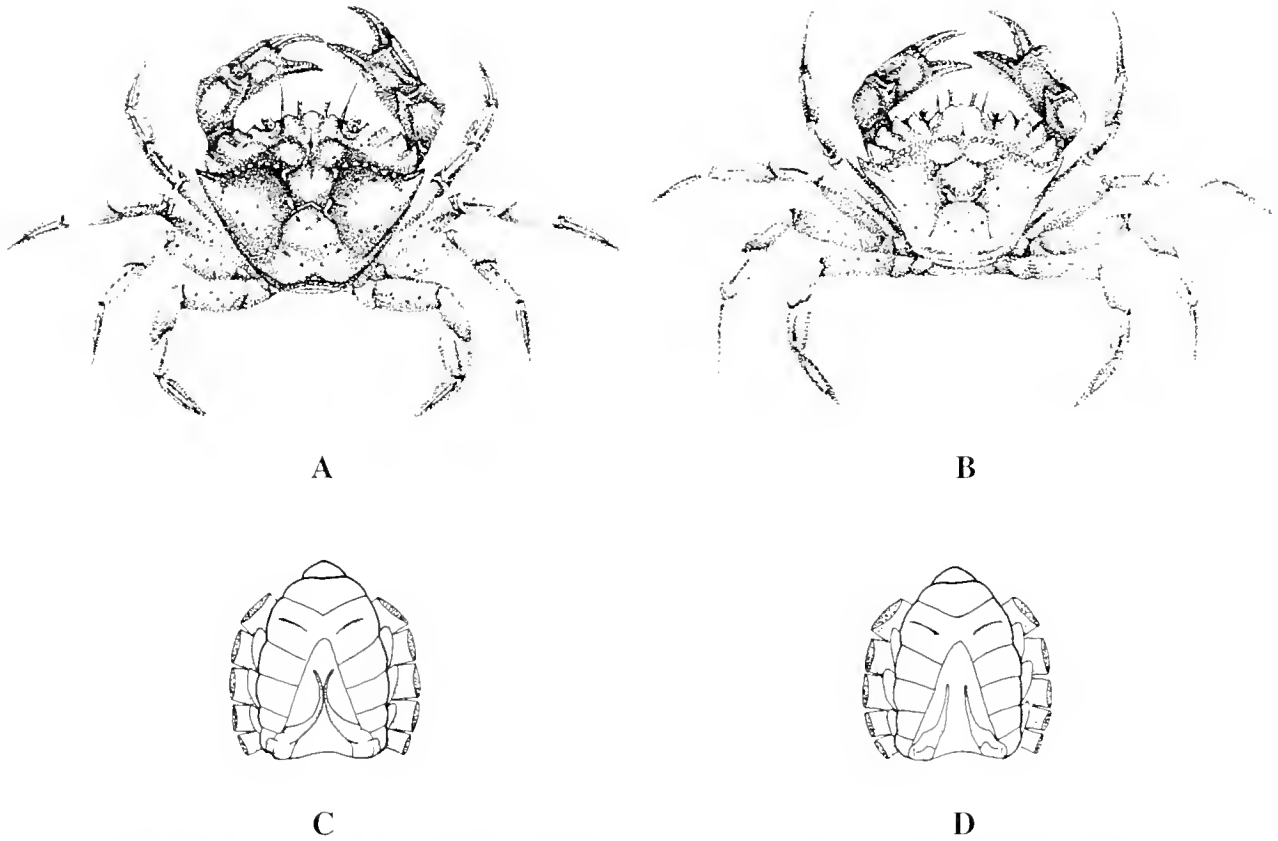

Figure 1. Distinguishing features of male specimens of *C. maenas* and *C. aestuarii*. Dorsal view of *C. maenas* (A) and *C. aestuarii* (B). Note that the carapace of *C. maenas* is wider than that of *C. aestuarii*. Typically, the frontal area of *C. maenas* is scalloped-shaped with distinct "bumps", while that of *C. aestuarii* is flatter and protrudes. The posterior-lateral margin of the carapace in *C. maenas* is generally convex and the 5th anterio-lateral tooth appears to point forward. The posterior-lateral margin in *C. aestuarii* is concave, while the 5th tooth is more elevated and appears to point outward. The legs of *C. maenas* appear shorter and thicker than those of *C. aestuarii*. Ventral view of breastplates with abdomen removed show the male copulatory appendages (pleopods). Note that the male pleopods are crescent-shaped in *C. maenas* (C) and straight and parallel in *C. aestuarii* (D). (Figure by Laura Hauck, reproduced with permission of Oregon Sea Grant.)

specimen we prepared a data sheet and noted which of the characteristics in Table 1 could be used as a diagnostic tool in a field setting. For a feature to be useful, it had to be visible to the naked eye (or through a hand lens) and measurable with vernier calipers.

RESULTS

Demeusy and Veillet (1953) and Demeusy (1953, 1958) draw attention to a suite of characters that distinguish green crabs from the Atlantic and Mediterranean coasts of France (Table 1). They obtained specimens from Sète in the Mediterranean and from La Manche (the English Channel) and Roscoff on the Atlantic (Fig. 2). They note that Mediterranean crabs are generally smaller, hairier, and possess a narrower and thicker carapace than Atlantic crabs. Almaça (1961) expands this comparative study by adding populations from the Spanish Mediterranean and the Spanish, Portuguese, and French Atlantic coasts (Fig. 2). While some of the characteristics were conserved across the larger sampling area, others, such as the distribution of hair on the carapace, frontal areas, and claws, carapace texture, and the number of segments on the antennae, were not (Table 1). Almaça (1972) observed carapace shape of *Carcinus* specimens from his former study areas as well as specimens from Australia and Maine and confirms that, in general, Atlantic specimens have wider and flatter carapaces than Mediterranean ones. He quantified these features as the carapace width (CW) to carapace length (CL) ratio (CW/CL) and the CW to carapace depth (CD) ration (CW/CD). For example, CW/CL is defined as the distance between the tips of the 5th anterio-lateral teeth divided by the distance between the central lobe of the frontal area and the posterior border of the carapace. CW/CL in *C. maenas* (≥20 mm) varied from 1.27 to 1.35, while that in *C. aestuarii* varied from 1.24 to 1.27. The CW/CD for males ≥20 mm was 2.27 to 2.57 for *C. maenas* and 2.25 to 2.31 for *C. aestuarii* (Table 3).

Zariquiey Alvarez (1968) provides a key for distinguishing the two species and includes photos of carapace shapes and male pleopods and a table of CW/CL for various size classes of both species and sexes (Table 4). The shape of the male pleopods is very diagnostic in separating adult Mediterranean from the Atlantic specimens (Fig. 1; Tables 1 and 2). When the abdomen of a male crab is lifted, the copulatory appendages, formed from the first two pairs of pleopods, become visible. The pleopods of *C. maenas* curve outward in a crescent shape with the centers of the crescents touching each other. Those of *C. aestuarii* form straight, parallel lines and do not touch. While size and sex appears to affect relative CW, the difference in the CW/CL between the species (for crabs ≥20 mm) is significant: 1.30 to 1.35 for *C. maenas* and 1.23 to 1.27 for *C. aestuarii* (Table 4). Rice and Ingle (1975) confirm

TABLE 1.

Morphological features useful for distinguishing *C. maenas* and *C. aestuarii* in the field. 1, Demeusey and Veillet 1953; 2, Demeusy 1953; 3, Demeusy 1958; 4, Almaça 1961; 5, Zariquiey Alvarez 1968; 6, Almaça 1972; 7, Rice and Ingle 1975; 8, Rasmussen 1973; 9, Noël 1992; 10, Furota 1999; 11, G. Jensen and C. Hieb, unpublished data; 12, Clark et al. 2001; 13, this study.

Feature	*C. maenas*	*C. aestuarii*	Comments
Native Distrubution (4,5)	Western Baltic, North Sea, Atlantic from Norway and Iceland to Morocco and Mauritania	Mediterranean, Black Sea, Asow Sea	Yes, for specimens within native range, (some mixing near Strait of Gibraltar)
Male pleopods (copulatory appendages) (4, 5, 9)	Crescent-shaped, touch at the bend	Parallel and straight, don't touch	Yes, Figure 1 (Fig. 115 in 5)
Posterior (5th) pair of teeth of anterio-lateral region of carapace (3, 5, 7, 13)	Appear to point forward	Appear to slant outward, tooth and central rib are elevated	Mostly, Figure 1, Teeth of some Atlantic specimens also slants outward (4)
Posterior-lateral margin of carapace (13)	Straight or convex	Concave	Mostly, Figure 1, But margin was concave in Atlantic specimen from Rabat, Morocco
Carapace width to length ratio (CW/CL) for crabs ≥20 mm (5, 6, 7, 9, 12, 13)	Wider carapace 1.29–1.36	Narrower carapace 1.22–1.27	Yes, Figure 1, Tables 2 and 3
Carapace width to depth ratio (CW/CD) (6, 12)	Thinner carapace 2.32–2.50	Deeper carapace 2.19–2.26	Shows great promise as a discriminator
Appearance of dorsal surface of carapace (1, 3)	Smooth and uniform	Cardiac, hepatic and brachial regions divided by deep furrows; rough with hairy projections	Not noticeable for preserved specimens (13)
Margin of frontal area between the eyes) (3)	Few or no bristles	Three size classes of bristles line the border of the frontal area	No (4, 7) Not noticeable for preserved specimens (13)
Shape of three lobes in frontal area (between the eye sockets) (5, 7, 13)	3 distinct "bumps", margin scalloped, frontal area does not protrude	Flatter, "bumps" not as distinct, frontal area protrudes beyond eyes	Yes, Figure 1 (Fig. 115 in 5, Plate 1 in 7) Toshio Furota, unpublished data
Segmentation of first antennae (3)	5–6 segments	4 segments	No, feature varies with size of animal (4)
Second antennae (3)	Fewer segments	Longer, more segments	No (4)
Orientation of teeth at the base of the second antennae (3)	On ventral side	On dorsal side	No (4)
Outer margin of claws (3)	Smooth	Hairy with bumps	No (13)
Tooth on inside of carpal (5)	Blunt	Sharp	No, (7, 13)
Presence of a fringe of long hair on the carpal ("wrist" segment) of claw (3)	No	Yes	No, some Atlantic specimens also possess this feature (4)
Length of legs	Shorter	Longer and more slender	Possibly, Figure 1, (Fig. 115 in 5) No (4)
Abdomen of same sized immature females (2)	Narrower	Wider (mature at a smaller size)	No, would be difficult to quantify
Carapace width of female in last prepuberty state (2)	22.5 mm	14 mm	No, great variability (d'Udekem d'Acoz, unpublished data)
Carapace width of females after puberty molt (2, estimate based on 35% growth increment with molt)	28–30 mm	16–19 mm	No, in Portugal ovigerous *female C. maenas* can be 15 mm and smaller (Kuris, unpublished data)
Maximum carapace width (5, 8, 10, 11)	>90 mm	65 mm	No, maximum size is not reached in many locations.

these species difference in CW/CL. The ratios for two female *C. maenas* from Plymouth, U.K. are 1.29 and 1.32, while that for a female *C. aestuarii* from Tunis, Tunisia is 1.25 (Table 3).

Clark et al. (2001) carried out the most statistically sound and geographically extensive study of carapace shape in *Carcinus*. They sampled 17 populations from the Atlantic, one from California, and eight from the Mediterranean and measured CW, CL, and CD for a total of 1,737 specimens. While the carapaces of the Atlantic and California populations were significantly wider and thinner than those of from the Mediterranean, there was also great variation between and within populations of a region. For example, the mean CW/CD for Atlantic populations varied from 1.27 to 1.32 and that for Mediterranean populations from 1.23 to 1.27. Standard deviations around the population means were over 0.02 (Table 3).

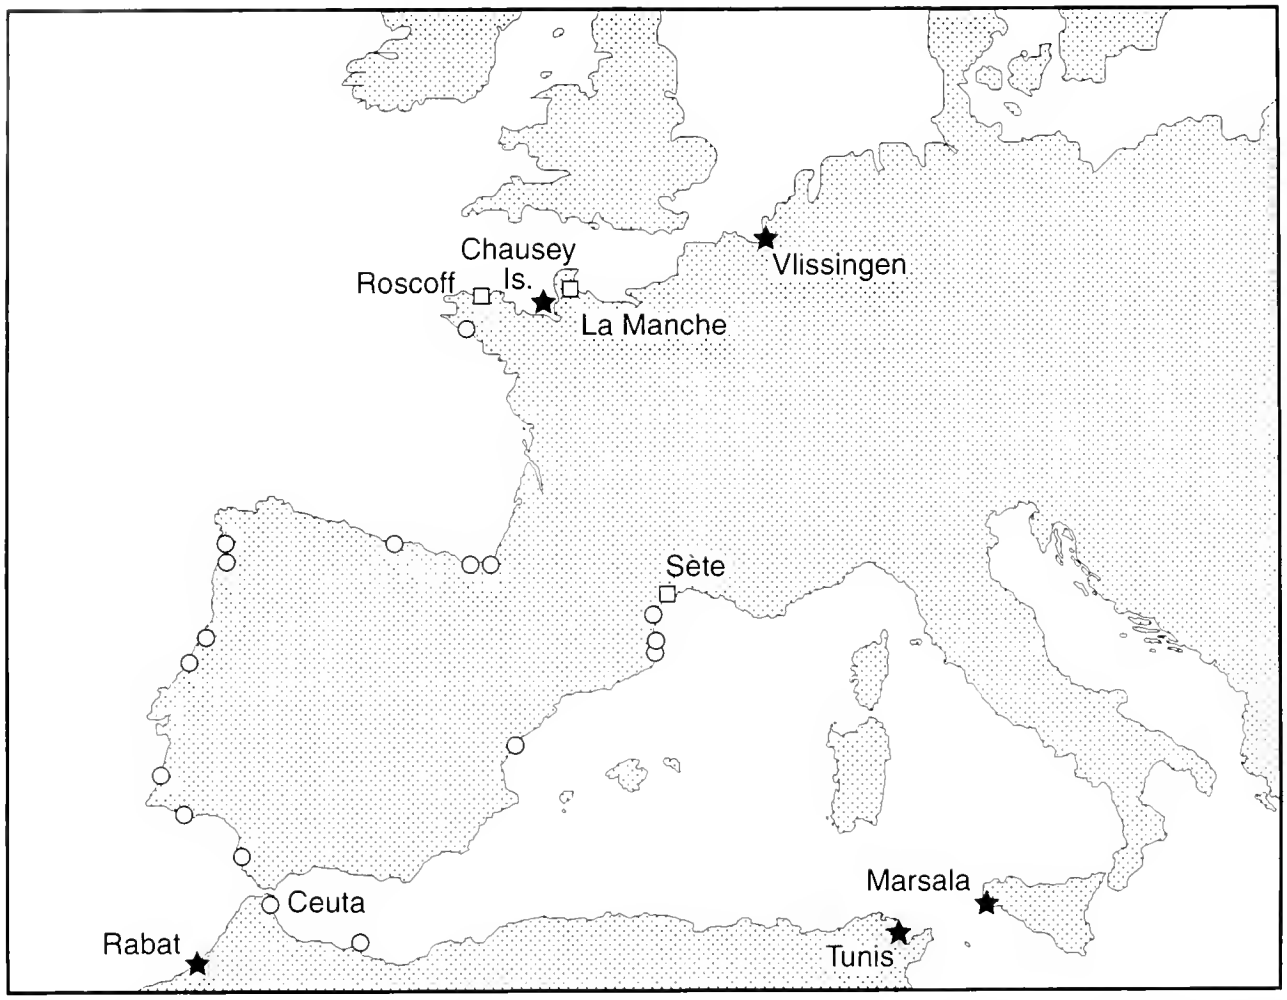

Figure 2. Location of collecting sites for Atlantic and Mediterranean populations of *Carcinus*. The study sites of Demeusy and Veillet (1953) and Demeusy (1953, 1958) are indicated by open squares and include Sète in the Mediterranean and La Manche (English Channel) and Rostcoff in the Atlantic. Almaça's (1960) study sites are indicated by open circles. Sites for museum specimens are indicated by dark stars and include Marsala and Tunis in the Mediterranean and Rabat, Chausey Islands and Vlissingen in the Atlantic.

The authors point out that it may not always be possible to correctly assign any one specimen to a species. They found less overlap in the mean CW/CD ratio: Atlantic populations varied from 2.32 to 2.50 and Mediterranean populations from 2.19 to 2.26 (Table 3).

Our study of a limited number of museum specimens from Europe and North Africa and fresh specimens from Oregon supports many of the previous findings. The shape of the male pleopods appears to be a good diagnostic field characteristic for separating adult males into the Atlantic and Mediterranean forms (Fig. 1; Table 2). The pleopods of *C. maenas* curve outward in a crescent shape with the centers of the crescents touching each other. Those of *C. aestuarii* form straight parallel lines and do not touch. All Oregon specimens clearly display the *C. maenas* pattern (Table 2). Another diagnostic feature is CW/CL. For our limited sample, we found that if the ratio is $\geq$1.29, then the specimen is *C. maenas*; if it is between 1.25 and 1.29, it is *C. aestuarii* (Table 2). Unfortunately, we failed to measure CW/CD ratio before returning our museum specimens.

After reviewing a previous version of this manuscript, Toshio Furota kindly supplied us with Table 5. This data set of carapace dimensions of *C. aestuarii* was collected by him and his coworkers while they were studying the life history of this species in Tokyo Bay (Furota et al. 1999). Furota states: "Results in morphological characteristics, including male pleopods and frontal area, clearly support that the samples are *C. aestuarii*." Both females exhibit a CW/CL ratio of under 1.27 and thus would be classified as *C. aestuarii*. One of the males exhibits a CW/CL of 1.31. While this value is not typical for *C. aestuarii*, it is within the range observed by Clark et al. (2001) (Table 3). The CW/CD ratios of 2.33 to 2.45 for three of the males, however, is unusually high for *C. aestuarii*. Almaça (1972) and Clark et al. (2001) found that CW/CD ratios of over 2.32 are characteristic of *C. maenas* (Table 3). The reasons for this discrepancy are unknown. Since CD is more difficult to standardize than CW and CL, Furota may have measured the crabs in a different part of the body than Clark et al. (2001). If, however, the difference remains after a larger sample size of crabs is examined using standard criteria, then a hybrid population may be present in Tokyo Bay.

We found that the shape of the lobes in the frontal area between the eye sockets tends to vary between the species. The three lobes of *C. maenas* possess distinct "bumps" and form a scalloped mar-

TABLE 2.

Morphological features of European and North African museum specimens and live crabs collected from Yaquina Bay, Oregon. CW/CW = carapace width divided by carapace length. An asterisk indicates that frontal area for the Moroccan specimen was difficult to categorize.

gin between the eyes. The lobes of *C. aestuarii* lack distinct "bumps" and do not form a scalloped margin. The frontal area in *C. aestuarii* is flat and protrudes beyond the eyes (Fig. 1). Our specimen from Morocco was the only one that we found difficult to characterize. The three lobes did not have distinct bumps nor did the frontal area protrude beyond the eyes. The frontal areas of the introduced green crabs in Tokyo Bay are flat and protruding, supporting the view that the specimens are *C. aestuarii* (Table 5).

While male pleopods, carapace ratios, and the shape of the frontal area are good field characteristics for discriminating the two *Carcinus* species, other features can provide supportive evidence (Table 1). The fifth anterio-lateral teeth in *C. aestuarii* possess a higher central rib and appear more elevated than in *C. maenas*. The posterior-lateral margin of the carapace leading up to the 5th tooth tends to vary between the species. Typically, the margin is convex or straight in *C. maenas* and concave in *C. aestuarii* (Fig. 1). Thus, the fifth teeth appear to point forward in *C. maenas* and outward in *C. aestuarii*. While these features generally hold true, there can be exceptions. Our specimen from Rabat exhibits the typical concave pattern of *C. aestuarii*, but the straight pleopods of *C. maenas*.

TABLE 3.

Summary of carapace ratios of *C. maenas* and *C. aestuarii* observed by various researchers. Asterisks draws attention to the unusually high ratios for *C. aestuarii* from Tokyo Bay.

The walking legs appear longer and more slender in *C. aestuarii* than in *C. maenas* (Fig. 1). While the carapace drawings are based on a composite of two specimens per species, great care was taken to correctly depict the relative proportions of the lengths and widths of all the limb segments. We feel that further investigation into a leg length to CL index might yield an additional diagnostic feature.

The last three distinguishing characteristics are related to life history features and are not useful in identifying crabs in the field. Sexual maturity in female *Carcinus* can be easily determined by simply attempting to lift the abdomen with a probe. If the abdomen is locked to the thorax, the female is immature, but if it lifts, she is mature. Males will mate with females prior to their puberty molt. Demeusy (1953) found that the smallest mated female *C. maenas* from the Atlantic coast of France was 22.5 mm in CW, while the smallest *C. aestuarii* from Sète in the Mediterranean was 14 mm. After molting, their CWs would be 28 to 30 and 16 to 19 mm, respectively (Table 1). Sexual maturity in *C. maenas* from Northern Europe, Maine, and Oregon typically occurs at a carapace width of 25 to 35 mm (Berrill 1982, Mohamedeen & Hartnoll 1989, d'Udekem d'Acoz 1993, Yamada 2001). Great variation in this feature, however, exists with females maturing at a smaller size in the fall than in the spring (d'Udekem d'Acoz 1993). In

TABLE 4.

Mean carapace width to length ratios (CW/CL) for male and female *C. maenas* and *C. aestuarii* of various size categories. Numbers in brackets give sample size. Data taken from Zariquiey Alvarez 1968.

TABLE 5.

Carapace dimensions and characteristics of male pleopods and frontal area of green crabs collected from Shinhama lagoon in Tokyo Bay on May 5, 1999. This data set was provided by Toshio Furota. An asterisk indicates an unusually high ratio for *C. aestuarii* when compared with Mediterranean populations studied by Clark et al. (2001).

Sex	Carapace Width (mm)	Carapace Length (mm)	Carapace Depth (mm)	CW/CL	CW/CD	Male Pleopod Orientation	Frontal Area	Species
Male	51.7	39.5	22.1	1.31*	2.34*	Straight	Protrudes	*C. aestuarii*
	54.5	24.3	24.3	1.28	2.24	Straight	Protrudes	*C. aestuarii*
	53.6	42.3	23.9	1.27	2.24	Straight	Protrudes	*C. aestuarii*
	49.0	39.0	23.0	1.26	2.13	Straight	Protrudes	*C. aestuarii*
	46.5	36.3	19.0	1.28	2.45*	Straight	Protrudes	*C. aestuarii*
	39.4	31.6	16.9	1.25	2.33*	Straight	Protrudes	*C. aestuarii*
Female	29.9	23.9		1.25			Protrudes	*C. aestuarii*
	36.3	29.2		1.24			Protrudes	*C. aestuarii*

Belgium, the smallest mature female was only 22.1 mm, while the largest, in its pre-puberty molt, was 38.8 mm (d'Udekem d'Acoz, unpubl. data). In Mil Fontes, Portugal, *C. maenas* females 15 mm and smaller have been observed to carry eggs (Kuris, pers. comm.). Mori et al. 1990 report that size of sexual maturity for *C. aestuarii* from Sardinia occurs around 29 mm. Thus, size at sexual maturity of the female cannot be used to distinguish the two species of *Carcinus*. Maximum size attained by *C. maenas* is over 90 mm and 65 mm for *C. aestuarii* (Table 1). Since maximum size is not reached in many locations, this feature would be of limited usefulness in distinguishing the species.

DISCUSSION

While *Carcinus* populations exhibit variation from site to site, the greatest discontinuity in morphological and genetic features occurs near the Strait of Gibraltar. Morphological and genetic studies support the view that the Atlantic *C. maenas* and the Mediterranean *C. aestuarii* diverged from a common ancestor, but may still be subspecies rather than true species (Almaça 1961, Bulhnheim & Bahns 1996, Clark et al. 2001). The Strait of Gibraltar with its high sill prevents water masses of the Atlantic and Mediterranean from freely intermixing, thus creating two basins with distinct water chemistry. Some surface water, however, does flow from the Atlantic into the Mediterranean and some deeper, high-saline water does flow from the Mediterranean into the Atlantic (Hopkins 1985). Thus, the Strait of Gibraltar acts only as a partial barrier to larval and gene exchange (Almaça 1989, d'Udekem d'Acoz 1999). For example, Almaça (1961) reports *C. aestuarii* morphs from the Atlantic Canary Islands and *C. maenas* morphs from Ceuta, just inside the Mediterranean (Fig. 2). Hybridization may explain why our specimen from Rabat, Morocco exhibited features of both species. Furthermore, evidence is accumulating that a hybrid zone may exist on the southeastern coast of the Iberian Peninsula. Further studies are needed to clarify the extent of any gene exchange between the two forms near this region of contact.

From studying the literature and from examining specimens from Europe, North Africa, and Oregon, we conclude that in most cases, adult *C. maenas* and *C. aestuarii* can be distinguished in the field by the shape of the male pleopods, the frontal area, and the CW/CL. The pleopods of *C. maenas* curve outward in a crescent shape with the centers of the crescents touching each other. Those of *C. aestuarii* form straight, parallel lines and do not touch. The Oregon specimens exhibit *C. maenas*-shaped male pleopods. While male pleopods are diagnostic in species identification, one needs to be aware of some special circumstances when they are not. For example, when male *C. aestuarii* are parasitized by the castrating barnacle, *Sacculina carcini*, the pleopods are often curved (Noël, pers. comm.). Almaça (1961) cautions that pleopods may not be diagnostic in immature males before the pleopods harden. He states: "The thin pleopods of immature Atlantic specimens can be as straight as those from the Mediterranean."

We found that the shape of the three lobes in the frontal area between the eye sockets tends to vary between the species. The three lobes of *C. maenas* possess distinct "bumps" with a scalloped margin between the eyes. The lobes of *C. aestuarii* are flatter, less distinct, and protrude beyond the eyes. The frontal areas of the introduced green crabs in Tokyo Bay are flat and protruding, confirming that the specimens are *C. aestuarii* (Furota, pers. comm.). All of our specimens, with the exception for the one from Morocco, were correctly categorized to species using this feature. This observation supports the view that hybridization may occur near the Strait of Gibraltar.

Another distinguishing feature is that the carapace of adult *C. maenas* is wider than that of *C. aestuarii*. This feature can be quantified as the CW/CL ratio. Zariquiey Alvarez (1968) finds that for each size and sex category, *C. maenas* has a larger CW/CL ratio than *C. aestuarii* and that *male C. maenas* typically have larger CW/CL ratios than females. This sex difference in adult *C. maenas* was also observed by Shen (1935) who reports a CW/CL of 1.31 for males and 1.29 for females. Studies by Almaça (1972), Rice and Ingle (1975), Clark et al. (2001), and this study confirm the observation that *C. maenas* has a larger CW/CL than *C. aestuarii* (Table 3). Clark et al. (2001) point out that because of natural variability within a population, it is not always possible to accurately identify any one specimen. However, if an adult *Carcinus* specimen exhibits a CW/CL of over 1.29, it most likely is *C. maenas*; if it exhibits a CW/CL of under 1.27, it most likely is *C. aestuarii*. Two of our specimens from Tunis with CW/CL just under 1.29 would have presented a classification problem had it not been for their distinct straight pleopods and flat, protruding frontal areas. Female *Carcinus* with borderline CW/CL ratios, however, would be difficult to classify to species.

The great variability observed in the CW/CL of the introduced *C. aestuarii* in Tokyo Bay could support an hypothesis proposed by Geller et al. (1997) that this population is composed of hybrids. Molecular genetic analysis revealed mitochondrial haplotypes

characteristic of both species. The authors suggest either that the population originated from the hybrid zone near the Strait of Gibraltar or that more than one species has been introduced into Tokyo Bay. A subsequent analysis using microsatellite DNA did not support the multiple-invasion hypothesis for this population (Bagley & Geller 2000). Clearly, more research is needed to clarify the origin of this introduced population of *Carcinus*.

While the two sibling species of *Carcinus* may look alike, it is possible to distinguish them in the field using the above morphological criteria. By incorporating the three defining characteristics, those of the shape of the male pleopods, the shape of the frontal area between the eye sockets, and the CW/CL ratio, successful field differentiation between these two species can be achieved in most cases. Other features, such as the orientation of the 5th antero-lateral spine and the curvature of the posterior-lateral carapace margin are not diagnostic, but can provide supporting evidence for species identification.

We believe that two additional features hold great promise as good species discriminators. We propose that the CW/CD ratio and the relationship of the length and width of the walking legs to CL be investigated. Furthermore, we suggest that greater discrimination between the species could be achieved by taking the sexual difference in the carapace shape into account.

ACKNOWLEDGMENTS

Many people helped us in this study. The staff of the Oregon State University Valley Library and Susan Gilmont of the Guinn Library at Hatfield Marine Science Center provided us with pertinent articles. Paul Clark, Michael Neale, and Philip Rainbow of the Natural History Museum in London, Pierre Noël of the Natural History Museum in Paris, and Cédric d'Udekem d'Acoz, research associate at the Royal Institute of Natural Sciences in Brussels, kindly provided us with copies of their manuscripts. Toshio Furota of Toho University generously sent us carapace dimensions from the introduced population of *Carcinus aestuarii* in Tokyo Bay. Anthony Pires translated a critical passage from the original Portuguese, David Reinert provided the map, and Cheryl Bright and her staff of the Smithsonian Museum of Natural History sent us the European and North African green crab specimens. Comments by Hans-Peter Bulnheim, James Carlton, Paul Clark, Cédric d'Udekem d'Acoz, Toshio Furota, Jonathan Geller, Armand Kuris, Andrew Lohrer, and William Walton greatly improved this manuscript. We thank them all. This research was funded, in part, by the National Sea Grant College program of the U.S. Department of Commerce's National Oceanic and Atmospheric Administration under NOAA grant number NA76RG0476, project number R/NTS-2-PD.

REDUCING PREDATION ON MANILA CLAMS BY NONINDIGENOUS EUROPEAN GREEN CRABS

EDWIN GROSHOLZ,[1] PAUL OLIN,[2] BRIAR WILLIAMS,[3] AND RICO TINSMAN[3]

[1]*Department of Environmental Science and Policy, University of California, Davis, California 95616;* [2]*University of California, Sea Grant Extension Program, 2604 Ventura Avenue, Santa Rosa, California 95403;* [3]*Bodega Marine Laboratory, P.O. Box 247, Bodega Bay, California 94923*

ABSTRACT The introduced European green crab (*Carcinus maenas*) poses a potential risk for commercial production of Manila clams (*Venerupis philippinarum*), a growing fishery in western North America. We investigated methods for modifying commercial production of Manila clams in order to reduce losses to green crab predation. In both 1997 and 1998, the timing of the outplant of seed clams was varied such that one portion of the total clam production was outplanted early in the year (March) and another portion outplanted later in the year (August/September). In July and August 2000, we examined these bags outplanted in 1997 and 1998 and quantified the clam mortality and the abundance of crabs including green crabs. We tested the effects of both year of transfer (1997 vs. 1998) and the timing of transfer (early season vs. late season) on clam and crab abundance and found significantly ($p < 0.05$) fewer green crabs and less predation on Manila clams in bags that were outplanted in the late season. Year of outplant also influenced clam survival and green crab abundance, such that delayed outplant significantly ($p < 0.05$) increased clam survival only when green crab abundances were high (1997). Our data suggest that the increased Manila clam survival in delayed outplant bags was likely due to reduced green crab recruitment and consequently lower green crab predation. We conducted additional experiments on relative predation rates by green crabs on Manila clams. We found that green crab predation is strongly size dependent, and that while juvenile green crabs were not effective predators of market size Manila clams (>36 mm in width), these clams were easily consumed by adult green crabs (>50 mm carapace width). We conclude that in years of high green crab abundance, delayed outplant is an effective means of reducing losses of commercially produced Manila clams.

KEY WORDS: Manila clam, *Venerupis philippinarum*, European green crab, *Carcinus maenas*, predation, recruitment, nonindigenous

INTRODUCTION

More than 400 non-native species have become established in the coastal waters of the U.S., and many have resulted in substantial economic and ecological impacts (Ruiz et al. 1997, Cohen & Carlton 1998, Ruiz et al. 2000). In western North America, the recently introduced European green crab (*Carcinus maenas*, Linnaeus, 1758) now poses a potential threat to the commercial production of Manila clams (*Venerupis (Ruditapes) philippinarum*, A. Adams and Reeve, 1850) (see Carlton 1992 and Coan et al. 2000 regarding subspecies) and other invertebrate fisheries in western North America (Lafferty & Kuris 1996, Jamieson et al. 1998). Like green crabs, Manila clams are also non-native, having been accidentally introduced with Pacific oysters (*Crassostrea gigas*, Thunberg, 1795) in San Francisco Bay in the 1940s (Cohen & Carlton 1995). Manila clams now support a growing commercial fishery with landing revenues of approximately $10.5 million in 1999 for Washington (Pacific States Marine Fisheries Commission 1999) and increasing production in Oregon, California and British Columbia, Canada. European green crabs have the potential to become an important source of mortality for Manila clam producers throughout most of this range, where they have been reported from Morro Bay, CA to Vancouver Island, British Columbia since 1998, and have established populations between Monterey Bay, CA and Gray's Harbor, WA (Grosholz et al. 2000, G. S. Jamieson, unpub. data). In central California, where they first became established in San Francisco Bay in 1989, green crab predation has already resulted in losses of nearly 40% of the annual production of 5,500 kg for one producer in 1996 (John Finger, Hog Island Oyster Co., Marshall, CA, pers. comm.).

European green crabs are widely acknowledged as a pest species in other areas including Australia (Thresher 1997), South Africa (LeRoux et al. 1990, Griffiths et al. 1992), and the northeastern U. S., where they likely contributed to the demise of the soft-shell clam (*Mya arenaria* Linnaeus, 1758) fishery in New England in the early 1900s (Glude 1955, MacPhail et al. 1955, Ropes 1968). In its native range along the North Atlantic coast of Europe, green crabs are prodigious consumers of invertebrates in general, and bivalves in particular (Reise 1977, Scherer & Reise 1981, Jensen & Jensen 1985, Sanchez-Salazar et al. 1987, Rafaelli et al. 1989) and are one of the primary predators of Manila clams (Cigarría & Fernández 1998, Cigarría & Fernández 2000).

The method of commercial production is likely to influence rates of green crab predation on Manila clams. Several culture methods are used in this fishery depending on available space, substrate type, and local predators, include bag culture, and direct outplanting (Spencer et al. 1992). During the two to four years required to grow Manila clams to market size, they can be vulnerable to various threats including crabs, waterfowl, fouling organisms, and parasites (Laing 1993, Paillard & Maes 1994, Smith & Langdon 1998). After the losses to green crabs experienced by central California growers in 1996, there was a need to modify the bag culture methods commonly used for Manila clam production in central California, in order to reduce green crab predation.

The specific goal of this study was to investigate the effectiveness of delaying the timing of outplant of Manila clams for reducing predation by green crabs. Typically, hatchery reared seed clams are initially placed in small mesh "seed bags," then, after approximately one year, are transferred from the seed bags to larger mesh "growout bags." The original date of outplant into seed bags largely determines the timing of the transfer of clams from seed bags to growout bags, so that both outplant and transfer happen either early in the season (winter/spring) or later in the year (summer/fall) approximately a year apart. After transfer, clams remained in growout bags for typically two more years without any further management. We hypothesized that the timing of the

dates of outplant and transfer (hereafter referred to as outplant date) from early in the year (March) to later in the year (August/September) would reduce the number of green crabs that recruited into the Manila clam bags as megalopae or early instar juveniles. Since predation is cumulative during the time Manila clams spend in both seed and growout bags, our assumption was that reducing green crab recruitment into clam bags would reduce the abundance of predatory adult green crabs, thus resulting in higher survival of Manila clams at the time of harvest.

MATERIALS AND METHODS

Manila clams used in these experiments were grown in commercial culture by the Hog Island Oyster Company (HIOC), Marshall, CA, USA. The site for the delayed outplant experiment was Tom's Point in Tomales Bay (Marin Co.), CA (38°13′02″N, 123°56′49″W). The site has a muddy sand substratum and an annual temperature range of 10–20°C and a salinity range of 20–33 ppt. Salinity remains high during drier months from late spring through early fall (Cole et al. 1990 for additional site information on Tomales Bay).

To investigate size dependent predation of Manila clams by green crabs, we conducted an additional short-term experiment on the marine reserve of the Bodega Marine Laboratory, Bodega Bay (Sonoma Co.), CA (38°20′00″N, 123°2′30″W). This site has sandy-muddy sand substratum with a temperature range similar to Tomales Bay, but with salinity generally near full seawater. Additional site information can be found in Grosholz et al. 2000.

Delayed Outplant Experiment

The experiment consisted of two experimental treatments: the first treatment involved manipulating the timing of outplant (and transfer) and the second treatment was the year that the clams were first outplanted (either 1997 or 1998). Early outplant occurred in March (1997 and 1998) and late outplant occurred in September (1997) and August (1998). This resulted in bags being in the field exposed to crab predation for approximately the following number of days: 1,215 days (March 1997), 1,035 (September 1997), 850 (March 1998), 700 (August 1998). Outplanted seed clams (approximately 6 mm width) were held in seed bags (3 mm mesh bags, 1 m L × 0.6 m W × 0.3 m H) that were placed in rows on the substrate at a tidal height between approximately +0.3 m and +1.0 m. After approximately one year, clams (approximately 12 mm width) were transferred from seed bags to growout bags (6 mm mesh, 1 m L × 0.6 m W × 0.3 m H) and typically remained in growout bags for an additional two years until they reached commercial size. During this transfer from seed bags to growout bags, larger crabs and excess shell debris were removed, although smaller shore crabs such as *Hemigrapsus oregonensis* (Dana, 1851) were frequently missed and not removed during transfer.

Between July 2000 and September 2000, we examined bags that had been outplanted both early and late in 1997 and 1998. For each of the four different outplant periods, March 1997, September 1997, March 1998, and August 1998, we examined at least 20 Manila clam bags. For each bag, we recorded the number, size (carapace width to nearest mm), species, and gender of all crabs including European green crabs (*Carcinus maenas*), grapsid shore crabs including *Hemigrapsus oregonensis* and *Pachygrapus crassipes* (Randall, 1839), and cancrid crabs *Cancer productus* (Randall, 1839), *Cancer magister* (Dana, 1852), *Cancer antennarius* (Stimson, 1856). Also, we recorded the number of crushed clams by counting intact hinges and measuring a subset of the remaining live clams at the widest point on the shell to nearest mm. Shells crushed by green crabs were generally identified by characteristic shell damage at the growing edge of the shell. Since clams outplanted in 1997 were already market size, we examined these at the HIOC facility as they were being harvested for sale. However, since clams outplanted in 1998 were slightly smaller and not ready for harvest, we examined these in the field using the same data collection methods, and returned them to the field.

To address the possibility that differences in the relationship between shell thickness and shell width for clams outplanted early vs. late might contribute to differences in predation rates, we measured the shell width along the anterior-posterior axis and shell thickness at the posterior margin and at the pallial sinus for 100 intact shells from March 1998 and August 1998.

Size Dependent Predation Experiment

We conducted a second experiment in July 1999 to examine how the relationship between green crab size and Manila clam size influence predation rates under commercial culture conditions. Using commercial growout bags from HIOC, we placed 15 clams chosen from one of three size class treatments (<23 mm, 25–33 mm, or >36 mm) in commercial clam bags with one green crab chosen from one of three size class treatments (30–45 mm, 50–65 mm, or >70 mm). All experimental crabs for the two largest size classes were intermolt males, while for the smallest size class, because of the limited availability of intermolt males in this size range, we used half males and half females split evenly among clam size treatments. We used a fully factorial design with all treatment combinations yielding nine treatments (3 clam × 3 crab treatments) with each treatment replicated five times for a total of 45 experimental units (=clam bags).

We placed the 45 growout bags with experimental clams and crabs in five blocks placed at approximately 0.2 MLLW in Bodega Harbor anchored to the substrate following standard commercial outplant procedures. We anchored bags placed side by side and separated blocks by approximately 5 meters. After two weeks, we recovered all clam bags and counted and measured all clams and crabs.

Because there was no shell breakage or other physical evidence of crabs in the smallest size class preying on clams in the largest size class, we used this treatment as a conservative "control" treatment, for which we assigned mortality in this treatment as "non-predator mortality." We used this value for "non-predator" mortality (4%) to recalculate mortality for other treatments prior to analysis. Therefore, this correction of 4% reduces the between-treatment differences in mortality between bags with large, medium, and small crabs prior to statistical analysis. This resulted in more conservative between-treatment tests by making it more difficult to determine significant differences between treatment, thus reducing the probability of Type II error.

Statistical Analysis

For the outplant delay experiment, we conducted a two-factor analysis of variance (ANOVA) with year (1997 or 1998) crossed with outplant date (early or late) as main effects and the number of green crabs per bag and the number of preyed clams per bag as dependent variables. Separate post-hoc tests of treatment means were estimated with Tukey's studentized range test for each year.

To analyze the relationship between the number of green crabs per bag and the number of preyed clams across all outplant periods, we used linear regression with the numbers of green crabs and the numbers of preyed clams as paired variates for all outplant dates. We used linear regression to analyze the relationship between green crab abundance and several other variables including the number of preyed clams per bag, the number of *Hemigrapsus oregonensis* per bag, and the number of *Pachygrapsus crassipes* per bag. We also used linear regression to analyze the relationship between clamshell thicknesses on clam width for clams outplanted early vs. late in 1998. Lastly, to test for differences in size-specific shell thickness between treatments, we conducted independent linear regressions of shell thickness on shell width for both March and August 1998 clams (100 each) using ordinary least squares regression.

For the size-dependent predation experiment, we used a two-factor ANOVA with crab and clam size as main effects and clam survival as the dependent variable. As a limited test the effect of crab gender on clam mortality, we also analyzed data from this experiment in treatments with the smallest crab size class where we used equal numbers of male and female crabs. We used a t-test to compare differences in mortality for males vs. female crabs pooled across clam size treatments (n = 15).

The data for all ANOVAs were tested for homogeneity of variances and data were either square root transformed (counts), log-transformed (sizes), or arc-sin square root transformed (percentages) as needed to meet test assumptions. All statistical analyses were conducted with SAS 8.0 (Statistical Analysis Systems, Carey, NC).

RESULTS

Delayed Outplant Experiment

Overall green crabs were most abundant in bags outplanted in 1997 and were more abundant in bags outplanted early (March 1997) than late (September 1997) (Fig. 1). Both the outplant date ($F = 4.72$, $p < 0.05$) and year ($F = 16.3$, $p < 0.0001$) significantly affected the average number of green crabs per bag, and there was a significant interaction between outplant date and year ($F = 5.63$, $p < 0.05$). Post-hoc tests showed there was a strong affect of outplant date in 1997 with fewer crabs in clam bags on the later outplant date ($F = 6.8$, $p < 0.015$), but there was no significant effect of outplant date in 1998 ($F = 0.16$, $p > 0.60$) when overall green crab abundances for that year were lower (Fig. 1). Although the mean abundance of green crabs was low (mean 0.8 ± 0.66 crabs per bag in March 1997), only one green crab per bag may be necessary to produce large losses of clams (see later).

A strong treatment effect was evident with the percentage of crushed clams per clam bag being greatest in the March 1997 outplant group (mean 45.5% ± 21.4) (Fig. 2). Overall, there was a highly significant effect of both year ($F = 66.74$, $p < 0.0001$) and outplant date ($F = 31.08$, $p < 0.0001$) and there was a significant interaction as well ($F = 17.31$, $p < .0005$). Post-hoc tests also showed a strong affect of outplant date in 1997 ($p < 0.0001$), but not in 1998 ($p > 0.40$).

We also found a strong positive relationship between the number of green crabs per bag and the number of crushed clams, when data were pooled across outplant dates. Figure 3 shows that as the number of green crabs per bag increases, there was a significant increase in the number of preyed clams observed per bag ($n = 77$, $r^2 = 0.427$, $p < 0.001$). We also found that the abundance of *Hemigrapsus* was negatively associated with the abundance of green crabs. As Figure 4 shows, there was a significant negative relationship between the number of *Hemigrapsus* per bag and the number of green crabs per bag ($n = 81$, $r^2 = 0.20$, $p < 0.001$). Our analysis of the effects of year and outplant period on the number of *Hemigrapsus* showed a significant affect of year ($F = 7.39$, $p < 0.01$), no effect of outplant date ($F = 0.07$, $p > 0.70$), and a significant year by outplant date interaction ($F = 11.21$, $p < 0.005$).

The mean size of the clams in the growout bags varied as a function of outplant date (36.3 ± 4.9 mm March 1997, 34.1 ± 3.1 mm September 1997, 33.5 ± 2.9 mm March 1998, 32.4 ± 2.4 mm August 1998) (Fig. 5). Clams from early outplant date groups (March 1997 and March 1998) were significantly larger ($F =$

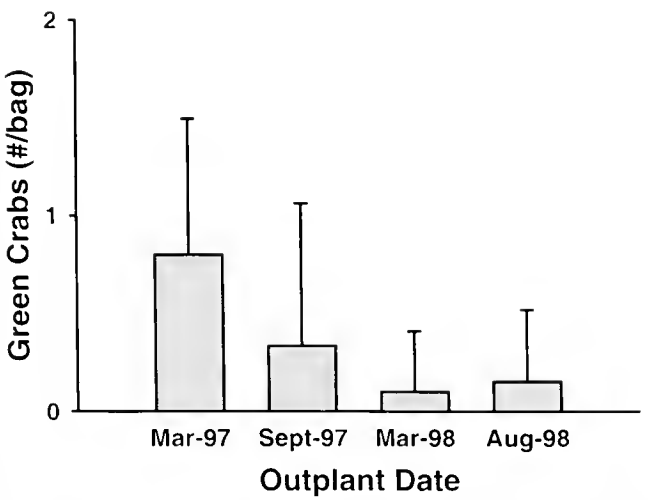

Figure 1. The number of green crabs observed per Manila clam bag for four outplant dates in outplant delay experiment (see text for total number of days in field). Bar heights represent the mean number of green crabs for 20 clam bags sampled from each outplant date. Error bars represent one standard deviation.

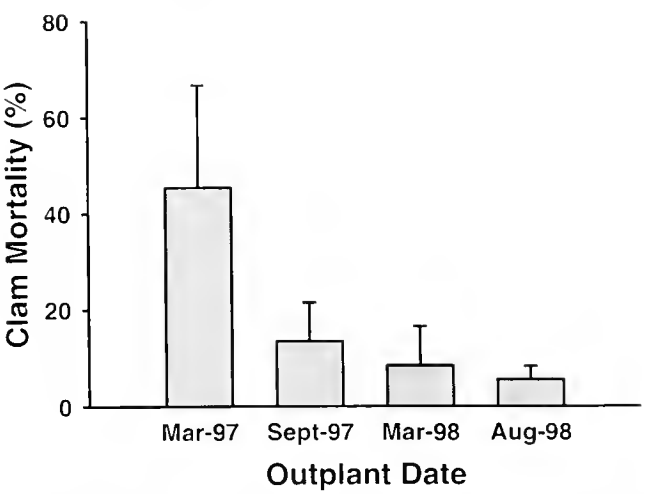

Figure 2. The percentage of crushed clams (=predation, see text) of total per Manila clam bag from four outplaot dates in outplant delay experiment. Bar heights represent the mean numher of crushed clams for 20 clam bags sampled from each outplant date. Error bars represent one standard deviation.

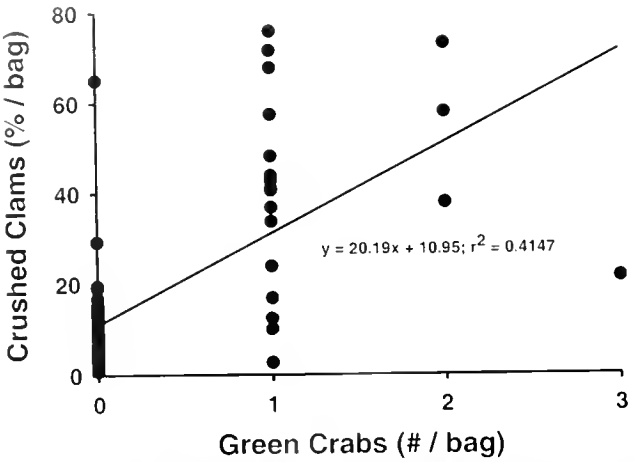

Figure 3. The number of crushed Manila clams versus the number of green crabs per Manila clam bag in the outplant delay experiment. Each point represents the total number of crabs and clams for each of twenty bags for all four outplant periods (March 1997, September 1997, March 1998, August 1998).

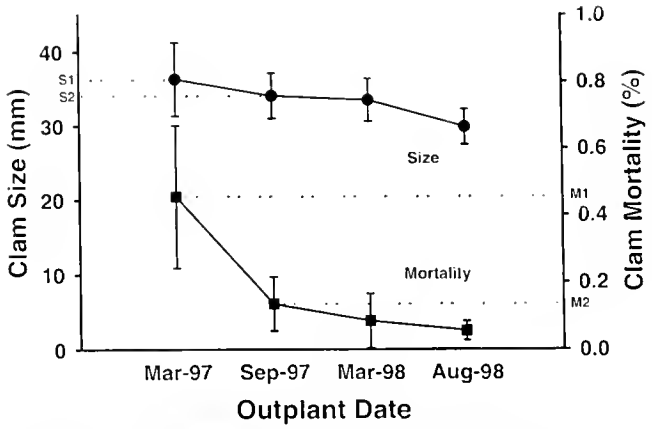

Figure 5. The size of Manila clams and the mortality measured in the delay outplant experiment. Each point represents the mean size of Manila clams (circles scaled on left axis) or mean percentage mortality of Manila clams (squares scaled on right axis) for each of twenty bags for all four outplant periods (March 1997, September 1997, March 1998, August 1998). The difference in mean clam size for March 1997 relative to September 1997 is indicated on the by S1-S2 on the left axis, and the difference in mean clam mortality for this same period is indicated by M1-M2 on the right axis.

15.3, $p < 0.001$) than clams from late outplant date groups (September 1997 and August 1998) and clams outplanted in 1997 were significantly larger (width) than clams outplanted in 1998 ($F = 27.8$, $p < 0.001$). These differences in mean size are the simple outcome of earlier initial outplant, thus more time to grow larger. These patterns of size variation, either as a function of outplant period or outplant year, indicate that our clam predation data are not simply the result of increased survival of larger clams, since the treatments with largest clams (March 1997) had the highest mortality.

These patterns in clam size resulting from different outplant times did not effect the relationship between clam size (width) and shell thickness. We found no significant differences in the relationship between shell thickness (in mm) measured at both the posterior edge, which was the portion of the shell typically crushed by crab predators, and shell width (in mm) measured as the maximum length along the anterior-posterior axis (Fig. 6). Neither slope was statistically different from zero ($p >> 0.10$). Using shell thickness measured at the pallial sinus gave the same answers. There was a slight trend towards longer shells having slightly thicker shells (although there were a small number of small, thick shells), but within the narrow size range of clams used in these experiments, this trend was not significant ($p > 0.60$ for March, $p > 0.20$ for August).

Lastly, green crab size and gender were similar between treatments (Table 1). There were with no significant differences ($p > 0.80$) among treatments in crab size and an increasing trend in crab sex ratio (male:female) with treatment date, although the low numbers of crabs in 1998 make these ratios a bit suspect.

Size Dependent Predation Experiment

The relative sizes of both green crabs and Manila clams influenced predation rates of Manila clams (Fig. 7). There was a sig-

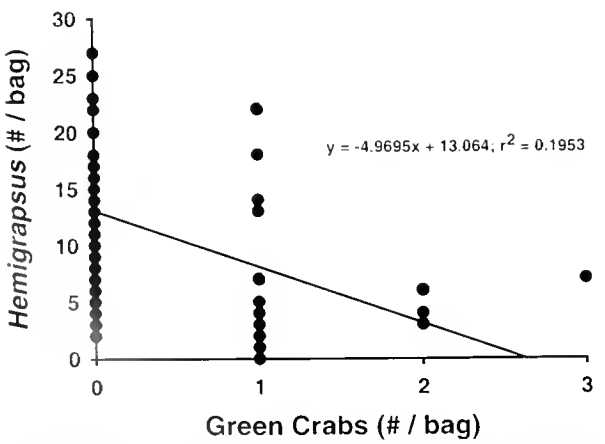

Figure 4. Number of green crabs observed per clam bag versus the number of native shore crabs (*Hemigrapsus oregonensis*) in outplants delay experiment. Each point represents the total number of crabs and clams for each of twenty bags sampled from all four outplant periods (March 1997, September 1997, March 1998, August 1998). Regression line is an ordinary least squares fit through all points with an unconstrained intercept.

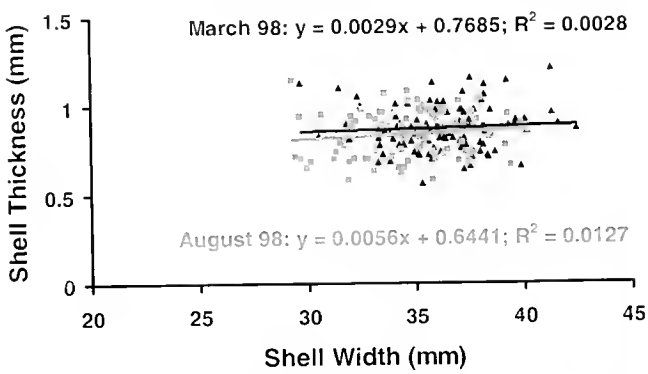

Figure 6. The relationship between shell thickness and shell width for Manila clams from two outplant dates (March 1998 and August 1998). Each point represents single measurements of thickness and width of a single shell from either March 1998 (black triangles) or August 1998 (gray squares). Regression lines for either March 1998 (black) or August 1998 (gray) are ordinary least squares fit through all points.

TABLE 1.

Abundance and size of male and female green crabs (*Carcinus maenas*) that recruited into Manila clam bags during the Delayed Outplant Experiment. For each outplant period (n = 20 bags), the mean and one standard deviation are shown for green crab abundance per bag (Mean # and S.D. #) and green crab carapace width (Mean CW and S.D. CW) for both males and females as well as male to female ration (M : F ratio).

nificant effect of green crab size ($F = 12.6$, $p < 0.0001$) and Manila clam size ($F = 6.37$, $p < 0.005$) and no significant ($p > 0.50$) interaction. We found that both medium and large green crabs preyed upon substantial numbers of large Manila clams. However, small green crabs (30–45 mm) were not able to prey on the large Manila clams (>36 mm) (Fig. 5) and no crushed shells were seen in any replicates in this treatment. We found no significant effects of crab gender with similar survival of clams in bags with male (mean 84% ± 13) vs. female crabs (mean 86% ± 15) ($t = -0.28$, $df = 13$, $p > 0.70$) using bags with the smallest crab size class (to compare males or females) pooled across clam treatments.

DISCUSSION

The main result was the strong effect of outplant timing on the number of crushed clams and the number of green crabs in clam bags. Clams outplanted early (March 1997) had higher numbers of green crabs and experienced greater losses than clams outplanted later (August 1997) (Fig. 1). These data suggest that in growout bags outplanted in March 1997, adult green crabs were capable of consuming an average of 45% of Manila clams, and in the most extreme cases, more than 70% (Fig. 2).

The regression analysis showed a significant ($p < 0.001$) positive relationship between increasing numbers of green crabs in growout bags and increasing numbers of crushed clams (Fig. 3). However, this relationship explained only about 40% of the variation in clam mortality, due largely to bags with "zero" crabs and substantial numbers of crushed clams. It is possible that the number of green crabs in these bags was initially higher, but unknown mortality may have resulted in fewer crabs per bag. Because the results show modest numbers of green crabs per bag (on average less than 1 green crab per bag) even for clams outplanted in March 1997 (Table 1), this suggests that the high mortality in the early-outplanted bags was produced by small number of crabs. In any case, the substantial numbers of crushed clams in these experimental bags underscores the potential impact that green crabs can have on clams in commercial culture. Although other factors can also produce substantial clam mortality, we are unaware of any that would cause the conspicuous shell damage observed along the margin of the shell (typically posterior margin) inside clam bags other than crab predation.

Another result from our study is that the effect of the timing of outplant was much smaller and not significant ($p > 0.60$) in 1998 in comparison with 1997, when overall green crab abundance were much lower. This suggests that the impact of green crabs may be variable between years, and if green crab recruitment is poor, as in 1998, there may not be sufficient green crab predation to justify the delay in outplant (and transfer) given some cost to delayed outplant in terms of growth (see Fig. 5).

The decreased predation in clam bags outplanted later may be partly the result of less total time spent in the field. In Figure 1, there is a positive relationship between the number of days the bags were in the field and the number of crushed clams. Given that the March 1997 treatment had been in the field for three recruitment seasons and the March 1998 treatment had been in the field for only two, it might be expected that the March 1997 treatments might have more crabs or the crabs may have attained a larger size.

The delay in outplant timing had a stronger effect on reducing predation than reducing clam size. As shown in Figure 6, we found a 70% reduction in mortality between clams outplanted in March 1997 (mean 45.5% ± 21.3) vs. September 1997 (mean 13.5% ± 8.0) (M1-M2 in Fig. 6), but only a 6% reduction in size between clams outplanted in March 1997 (mean 36.3 mm ± 5.0) vs. September 1997 (mean 34.1 ± 3.1) (S1-S2 in Fig. 6). Thus, the delayed outplant resulted in a substantial increase in clam survival, and therefore, commercial production, with a relatively minor reduction in clam size.

This differential effect on the number of days in the field on mortality vs. size likely reflects the possibility that green crab recruitment may not be as continuous throughout the year as predation. The number of spring/early summer recruitment seasons that a bag may experience may largely determine the number of crabs per clam bag. Green crabs are able to enter the growout bags only while they are smaller than the mesh, such as megalopae and early instar juveniles (generally CW <10 mm, thus carapace height <6 mm). In central California, most recruitment of early instar green crabs occurs during the spring and early summer (Grosholz et al. 2000, Grosholz, unpubl. data) and by late summer, most

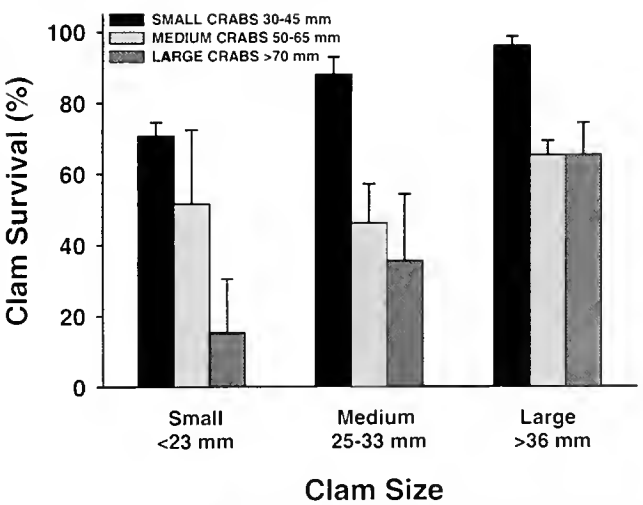

Figure 7. Percentage survival of Manila clams in the size dependent predation experiment. Bar heights represent the mean survival of clams for each of the nine treatment combinations (n = five bags per treatment). Error bars represent one standard error of the mean.

green crabs are too large to enter the growout bags. Therefore, clams bags outplanted in the fall would not generally be subject to recruitment by young-of-the-year green crabs, although they would be receive recruits in the following years.

The size dependent predation experiment provides additional support for green crabs being responsible for most of the clam mortality observed in the outplant delay experiment. Although green crabs in the smallest size class (30–45 mm CW) were not able to consume market-size clams (>36 mm), we found medium size crabs (50–65 mm CW) could consume Manila clams of any size in commercial production, so there was no size refuge from green crab predation (Fig. 7). Also, mortality of the largest clams was the same for both medium and large green crabs suggesting that green crabs in central California, which typically reach sizes exceeding 50 mm CW in their first year (Grosholz & Ruiz 1995, Yamada, in press), can consume the full range of clam sizes in commercial bags within a one year of recruitment. In addition, within the limited size range and small samples sizes involved in this experiment, we found no significant differences in predation levels between equivalently sized male and female green crabs ($p > 0.70$).

Although the outplant timing appears to have influenced clam mortality, many other characteristics of the crabs and clams in these experiments can influence the observed patterns of mortality. Previous work by Elner and Hughes (1978) Elner (1980, 1981), and Elner and Rafaelli (1980) have demonstrated that characteristics of crabs such as chelae size, sex, molt stage, etc. may interact with previous diet experience, temperature and other environmental factors to influence the rate and nature of predation. In the delayed outplant experiment, because we could not control the identity of the crabs in the clam bags (crabs recruited freely into bags), we were unable to control for differences among crabs. However, data for crab characteristics shown in Table 1 suggest that the differences in mortality among treatments were unlikely to have been influenced by differences in crab size or crab gender. The trends for crab size and gender among treatments opposed what might be expected if these factors were to have explained treatment differences in clam mortality.

The relative shell thickness of Manila clams might also have influenced the differences in clam mortality between treatments. However, as Figure 6 shows, there were no significant differences in the relationship between shell thickness and shell size (width) for early ($p > 0.60$) of late ($p > 0.20$) outplants treatments in 1997 with shell size explaining 1% or less of the variation in thickness overall ($R^2 = 0.003$ for early, $R^2 = 0.01$ for late). Therefore, difference in the timing of outplant did not produce changes in relative shell thickness.

In addition to the green crabs, there were other species of crabs recruiting into the clam bags including native shore crabs *Hemigrapsus oregonensis*, *Pachygrapsus crassipes*, and native *Cancer* spp. The *Cancer* spp. abundances were at very low abundance (<0.05 per bag) and *Pachygrapsus* were equivalently rare and unlikely to have had a measurable impact on the patterns. By contrast, *Hemigrapsus* were commonly found in the growout bags along with green crabs (overall 11.3 ± 6.9), although they rarely exceeded 20 mm in carapace width, and were also unlikely to have had a substantial impact on the number of crushed shells observed in the bags (Grosholz, unpubl. data). For example, the lowest *Hemigrapsus* abundance (mean per bag 7.30 ± 6.5) occurred in the outplant treatment with the highest clam mortality (March 1997) and the highest *Hemigrapsus* abundance (mean per bag 15.35 ± 6.34) occurred in the treatment with the lowest clam mortality in (March 1998, see Fig. 1).

We found that there were fewer *Hemigrapus* in 1997 when green crabs were more abundant, although the outplant date had opposing effects on *Hemigrapsus* abundance in different years. We also found a significant ($p < 0.001$) negative relationship overall between the abundance of *Hemigrapsus* and the abundance of green crabs (Fig. 4). Although adult *Hemigrapus* may prey on newly recruiting green crabs, the predatory relationship between these crabs may switch as green crabs approach adult size and prey on *Hemigrapsus* (Grosholz et al. 2000). The strong dependence of size as a determinant of intraguild predation among crabs has been amply demonstrated in western U.S. estuaries (Dumbauld et al. 1993, Iribarne et al. 1994).

In conclusion, our work demonstrated that decreased predation by green crabs on commercially produced Manila clams resulted from delaying the outplant timing of clams. We suggest that this low cost management tool could be used by Manila clam producers throughout western North America to reduce predation by green crabs in regions where green crabs are abundant. However, the specific timing of the delay needed to produce this result will likely vary with latitude, since the recruitment of green crabs is delayed with increasing latitude (Yamada, in press). Regardless, the Manila clam fishery would benefit by instituting low cost culture practices such as outplant delay, in order to avoid future losses to European green crabs.

ACKNOWLEDGMENTS

We thank the University of California Division of Agriculture and Natural Resources (DANR) for their support of Briar Williams through the RREA program and the Department of Environmental Sciences and Policy. We thank the Editor for her patience with revisions and two anonymous reviewers for their comments, which significantly improved the manuscript. In particular, we thank John Finger for implementing the outplant delay schedule into his Manila clam culture procedures to allow us to test our ideas about crab predation. We especially thank John and the staff of Hog Island Oyster Company for access to their properties, culture facilities, and Manila clam stocks and to the director and staff of Bodega Marine Laboratory for ongoing assistance and support.

RECOVERY OF THE WESTERN ROCK LOBSTER, *PANULIRUS CYGNUS*, FROM EMERSION AND HANDLING STRESS: THE EFFECT OF OXYGEN CONCENTRATION DURING RE-IMMERSION

B. J. CREAR[1,2]* AND G. N. R. FORTEATH[1]

[1]Tasmanian Aquaculture and Fisheries Institute, School of Aquaculture, University of Tasmania, PO Box 1214, Launceston, Tas. 7250, Australia; [2]Tasmanian Aquaculture and Fisheries Institute, Marine Research Laboratory, University of Tasmania, GPO Box 192B Hobart, Tas. 7001, Australia.

ABSTRACT The effect of dissolved oxygen concentrations (110–120, 90–100, 70–80, 50–60, 30–40 and 10–20% saturation) on recovery of *Panulirus cygnus* from a period of activity/emersion was investigated. Biochemical disturbances induced in *P. cygnus* by emersion and handling included a large decrease in the hemolymph pH (0.7 units) and an increase in the hemolymph lactate concentration (2.44 mmol L^{-1}). Re-immersion resulted in very high rates of oxygen consumption (up to 2.5 times the pre-emersion rate), elevated hemolymph glucose (1.1–4.5 mmol L^{-1}) and further increases in hemolymph lactate (2.7–11.1 mmol L^{-1}), with actual concentrations dependent on the dissolved oxygen concentration. Water oxygen concentrations of 50–60% saturation or less slowed the rate of recovery; all lobsters recovering in water with 10–20% oxygen saturation died within 12 hours. Based on the rate of recovery of physiological parameters, lobsters should be allowed to recover for a minimum of eight hours between stress episodes, whilst maintaining an oxygen concentration of 70–80% saturation or above.

KEY WORDS: activity, live holding, emersion, oxygen consumption, oxygen concentration, *Panulirus cygnus*, recovery, stress

INTRODUCTION

During the live handling of western rock lobsters (*Panulirus cygnus*) after capture, they are subjected to many conditions that are likely to cause stress. They are often exposed to air during which time they may be handled. Their response is to attempt escape by strong beats of the tail (tail flicking). This resultant stress can be expressed quantitatively by biochemical changes (blood pH, glucose, lactate) (Spanoghe 1997) and by the development of an oxygen debt (Crear & Forteath 2001). It is presumed that when lobsters are re-immersed, they are able to recover from any physiological disturbances caused by air exposure (Taylor et al. 1997). A variety of processes take place during re-immersion—energy pools (phosphagen and ATP) are recharged, anaerobic end products are cleared from the tissues and pH disturbances are corrected. An organism-level manifestation of all of the above, essentially cellular processes of recovery, is a period of supranormal oxygen consumption (the oxygen debt) (Ellington 1983). Generally, physiological disturbances are fully reversed within 24 hours of re-immersion.

An adequate period of recovery in water is necessary after each stage of handling or live transport to avoid compounding the stress syndrome (Taylor et al. 1997). European lobsters, *Homarus gammarus*, deprived of the opportunity to recover after an episode of stress were in a significantly worse state after a subsequent period of air travel than lobsters that had been allowed to recover (Whiteley & Taylor 1992). Since time between episodes of stress is often limited during post-capture handling of *P. cygnus*, optimising the speed of recovery becomes important.

Inadequately designed holding systems, overstocking and natural variability in the oxygen concentration of intake water can lead to low oxygen concentrations in live holding tanks. Concentrations as low as 35% saturation have been measured in tanks on board boats (Crear & Forteath 1997). As stressed lobsters have a high demand for oxygen, its availability is likely to influence both the duration and extent of recovery. Minimum dissolved oxygen concentrations recommended for lobster holding systems vary from 40 to 80% saturation (Beard & McGregor 1991, Forteath et al. 1993, Boothroyd 1994), however there appears to be no biological rationale for those recommendations. Additionally, oxygen supersaturation has been suggested as a possible tool to aid the recovery of lobsters (Forteath 1995). This paper examines the effect of dissolved oxygen concentration on the recovery of *P. cygnus* from a stress episode.

MATERIALS AND METHODS

Lobster holding conditions and respirometry are outlined in Crear and Forteath (2000). All experiments were conducted at the acclimation temperature of 23°C, which is close to the mean annual temperature of inshore waters inhabited by juvenile *P. cygnus* (Chittleborough 1975). In view of the relationship between oxygen consumption (VO_2 – $mgO_2/g/h$) and *P. cygnus* wet body weight (Crear & Forteath 2001), a restricted weight range (367–515 g) was used in the experiments. The following specific methods were used for this series of experiments.

The study was performed in two experimental series. The first series studied the oxygen consumption of lobsters recovering from a period of stress. Lobsters were removed from the holding tank and emersed for 30 minutes at an air temperature of 23°C. Continual disturbance (handling) for the first 5 minutes was followed by disturbance every 5 minutes (lobsters were maintained in an open foam box when not being handled). Lobsters showed strong escape behaviors (tail flicking) during the initial period of disturbance. The response diminished as the emersion time increased and after 30 minutes emersion the lobsters were normally unresponsive to disturbance. Six to twelve lobsters were tested at each of six oxygen concentrations (110–120%, 90–100%, 70–80%, 50–60%, 30–40%, 10–20%). The dissolved oxygen concentration was controlled as in Crear and Forteath (2000). As *P. cygnus* has a nocturnal oxygen consumption rhythm (Crear & Forteath 2001), all experiments were commenced before 0900 hours to ensure that none of the measurement periods fell during the night. Rates of V_{O_2} were calculated immediately after placing the disturbed lobsters in the respirometers (0 h), and after re-immersion for 1, 2, 4,

*E-mail: bradley.crear@utas.edu.au

6, 8 and 24 hours. Ten lobsters were used to determine standard VO_2 (control oxygen consumption rate).

The second series of experiments consisted of measuring the hemolymph parameters of lobsters over the same time-period and under the same dissolved oxygen concentrations as above. Lobsters were removed from the holding tank and disturbed for 30 minutes before being placed in water of known oxygen concentration. Hemolymph samples were obtained immediately after the disturbance period (0 h), and after re-immersion for 1, 2, 4, 8 and 24 hours. Dissolved oxygen was maintained within 5% of the designated concentration (Crear & Forteath 2000). Lobsters were sampled only once during each experimental run. They were replaced in the holding tank for a minimum of 48 hours before being used again (Waldron 1991). Control hemolymph parameters were determined for 12 lobsters: four taken directly from the holding tank at 0900 hours, and two further groups of four tested 8 and 24 hours later.

Hemolymph Sampling

Prebranchial hemolymph was sampled (1 mL) from the infrabranchial sinus via the arthrodial membrane at the base of a walking leg (usually the 3rd or 4th pair). The sample was withdrawn with an ice-chilled 1 mL syringe (Luer -Tuberculin) using a 21 gauge (Luer -21G*1.5) needle. Hemolymph samples were obtained anaerobically to ensure minimum mixing with air, since changes in CO_2 equilibrium can alter pH values (Vermeer 1987). The hemolymph sample was taken within 20 seconds of lobster capture, and immediately placed into an ice-chilled 1-mL Eppendorf tube. A 250-μL aliquot was deproteinated by adding it to 500 μL of ice-chilled 0.6 mol L^{-1} perchloric acid (PCA). The deproteinated sample was snap-frozen in liquid nitrogen and stored at −86°C for later measurement of lactate and glucose. The hemolymph remaining in the original tube was used for measuring pH.

Hemolymph Analyses

Hemolymph pH was measured with a calomel electrode (Activon Semi-Micro AEP336) connected to a pH meter (WTW pH 323). The probe was calibrated in buffer solutions chilled to the same temperature as the hemolymph samples (0°C). pH at 0°C varies from pH *in vivo* at ambient temperatures (0.49 units higher than at 23°C, Crear 1998), but this was an essential concession to retard clot formation (Vermeer 1987); clots formed within 5 minutes at ambient temperature.

The deproteinated hemolymph samples were centrifuged at 8000 g for 3 min. The supernatant (600 μL was generally obtained) was neutralized with 3 mol L^{-1} KOH (6.4 μL per 600 μL). The samples were stored on ice for 15 minutes before being centrifuged at 8000 g for 3 min so that the perchlorate precipitate could be removed. The supernatant (~550 μL) was either frozen (−86°C) for later analysis or analyzed immediately for lactate and glucose.

Lactate concentrations were determined enzymatically with the Boehringer-Mannhein analysis kit (Cat. No. 139084). The absorption was measured at 340 nm on a GBC UV/VIS 916 spectrophotometer. Glucose concentrations were determined with a Sigma glucose test kit (No. 510), which is based on the glucose-oxidase method. The absorption was measured at 450 nm on a GBC UV/VIS 916 spectrophotometer. New calibration curves were made up for each sample run and all assays were run in duplicate.

Statistical Analyses

Student's *t*-test was used to test for significant differences ($P<0.05$) between control and recovery values. Where appropriate, Student's *t*-test for samples with unequal variances was used. The one-way ANOVA was used to test for differences between treatments at each time-period. The Levene test was used to test for homogeneity of variance, and where necessary an appropriate transformation was performed before further analysis. Following ANOVA, means were compared by Tukey-HSD test. Correlation analysis was used to analyse the relationship between dissolved oxygen concentrations and lactate changes. The critical oxygen tension (P_c) was calculated (Cochran & Burnett 1996, Crear & Forteath 2000) from the oxygen consumption data immediately after re-immersion. All analyses were performed on the SPSS statistical package with α set at 0.05. All values are expressed as mean ± S.E.

RESULTS

There was no significant difference in the parameters measured for the control lobsters at 0, 8 and 24 hours, therefore the data were pooled. Survival was 100% in all treatments except for the 10–20% oxygen saturation, where no animals survived for more than 12 hours.

Oxygen consumption

In all treatments, apart from the 10–20% treatment, VO_2 was significantly higher after re-immersion than the control VO_2. From those high values, VO_2 reduced slowly over time (Fig. 1), with the pattern of recovery varying with the oxygen concentration. At high concentrations (90–100% and 110–120% oxygen saturation), VO_2 was not significantly different to the control VO_2 after eight hours re-immersion. In all other treatments recovery of VO_2 to control levels took longer, and in the 30–40% treatment, VO_2 remained significantly higher than the control VO_2 over the 24-hour re-immersion period. Lobsters in the 10–20% oxygen saturation treatment had significantly lower VO_2 than the control VO_2 at each measurement period.

Upon re-immersion, VO_2 rates varied with the oxygen concentration, being highest for the 110–120% and 90–100% oxygen saturation treatments (Table 1). At lower oxygen saturations, VO_2 decreased significantly with the dissolved oxygen concentration. From this data, P_c was calculated to be 63.1%.

The amount of excess oxygen consumed over the control rate during recovery also varied with oxygen concentration (Table 2). Lobsters recovered in water containing 70–80% oxygen saturation or higher consumed the least amount of oxygen during the recovery period. In comparison, lobsters in the 50–60% treatment consumed 1.3 times as much oxygen during the initial eight-hour recovery period and approximately twice as much oxygen in achieving full recovery (see Note b in Table 2). Lobsters in the 30–40% treatment consumed 0.75 times as much oxygen during the initial eight-hour recovery period, but had consumed 1.6 times as much oxygen after 24 hours although they had still not achieved full recovery.

Hemocymph parameters

Lobster hemolymph pH decreased significantly during the 30-minute disturbance period, from control concentrations of 8.36±0.01 to 7.66±0.03. In general, the pH returned to, or close to, the control concentrations after four hours of being re-immersed. However, during the first hour of re-immersion two distinct recovery patterns were noted: (a) at oxygen concentrations of 70–

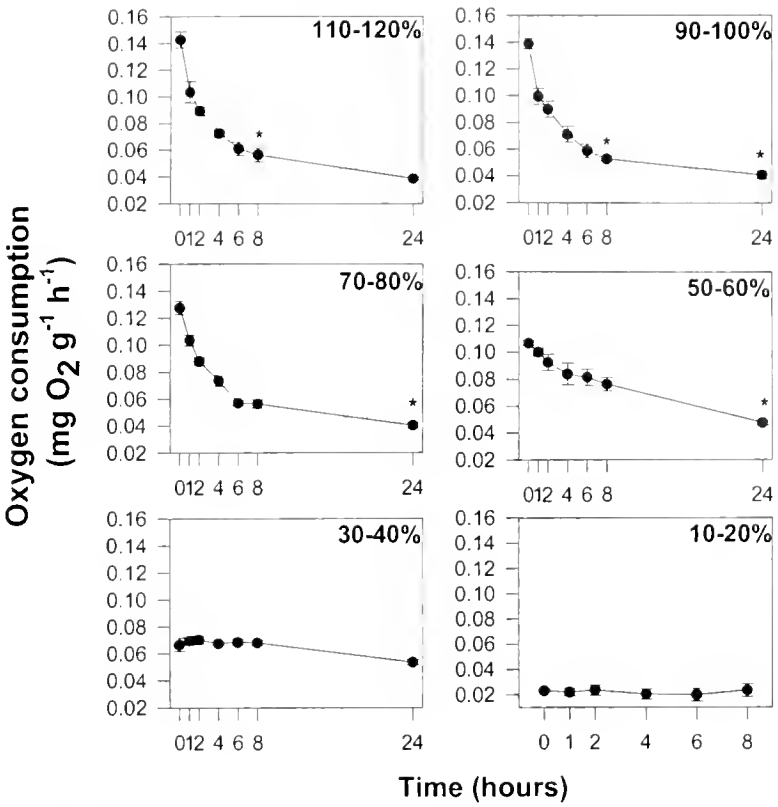

Figure. 1. Oxygen consumption (mg O_2 g^{-1} h^{-1})(mean ± SE) of the western rock lobster, *Panulirus cygnus*, over a 24-h period during "recovery" from disturbance (n = 6 to n = 12). The lobsters were disturbed (emersed and handled) for 30 minutes prior to re-immersion in water containing different concentrations of dissolved oxygen. Dotted line: control oxygen consumption rate (n = 10).*, not significantly different to the control. The lines are drawn for ease of viewing.

80% and higher the pH remained at the low level measured after the emersion period; whilst (b) at lower oxygen concentrations the pH increased markedly (Fig. 2, Table 3).

In some treatments (70–80, 50–60 and 30–40%) the pH increased to a significantly higher level than that of the control during the recovery period, however in all those treatments the pH was not significantly different to the control after 24 hours. The pH of lobsters in the 110–120% treatment was significantly lower than the control, and all other treatments, after 24 hours.

Hemolymph lactate increased significantly during the 30-minute disturbance period, from a resting concentration of 0.05 ± 0.02 mmol L^{-1} to 2.44 ± 0.37 mmol L^{-1} (Fig. 3). Lactate increased further during the first hour of re-immersion with the largest increases occurring at the lower oxygen concentrations (Table 4; Fig.

TABLE 1.

The results of the ANOVAs comparing oxygen consumption of lobsters (*Panulirus cygnus*) in each oxygen concentration treatment at each measurement time during the 24 h recovery period. Different letters denote significantly different results.

Oxygen Concentration (%)	Recovery Time (h)						
	0	1	2	4	6	8	24
110–120	a	a	a	ab	b	bc	b
90–100	a	a	a	ab	b	c	b
70–80	b	a	a	ab	b	bc	b
50–60	c	a	a	a	a	a	a
30–40	d	b	b	b	ab	ab	a
10–20	e	c	c	c	c	d	N/A

N/A - the lobsters in this treatment did not survive for 24 h.

TABLE 2.

The amount of excess oxygen consumed (mg O_2 g^{-1}) over the control rate during recovery lobsters (*Panulirus cygnus*) from emersion and handling. Oxygen consumed during 8-h and 24-h of recovery are shown.

Time	Dissolved Oxygen Concentration (%)					
	10–20	30–40	50–60	70–80	90–100	110–120
8 h	−0.163	0.184	0.334	0.251[c]	0.253	0.266
24 h	N/A	0.425[a]	0.593[b]	N/A	N/A	N/A

N/A not applicable to this time period at that particular dissolved oxygen concentration

[a] Oxygen consumption was still significantly higher than the control after 24 h so the total oxygen consumed during recovery would be slightly higher than this value.

[b] Oxygen consumption may have returned to the control prior to the 24 h period so this value may be an overestimation.

[c] Although the oxygen consumption was still significantly higher than the control after 8 h it was not significantly different to either the 110–120% or 90–100% rate. Therefore, the total amount of oxygen consumed was only calculated up to the 8 h mark.

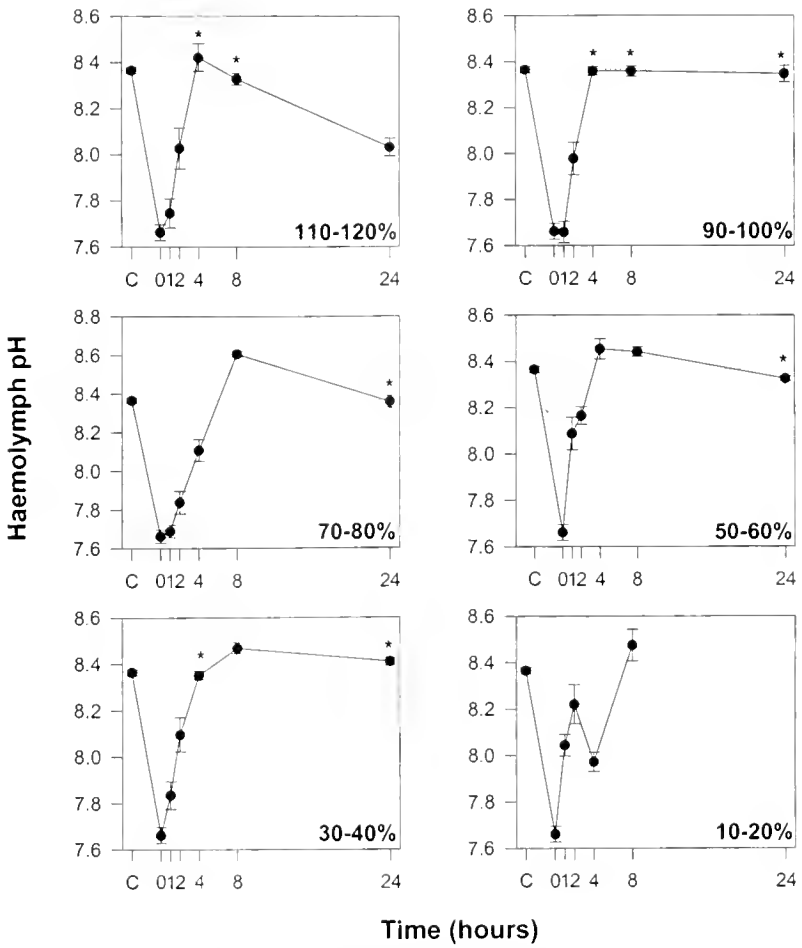

Figure. 2. Hemolymph pH (mean ± SE) of the western rock lobster, *Panulirus cygnus*, over a 24-h period during "recovery" from disturbance (n = 6 to n = 12). The lobsters were disturbed (emersed and handled) for 30 minutes prior to re-immersion in water containing different concentrations of dissolved oxygen. Dotted line: control hemolymph pH value (n = 12).*, not significantly different to the control (C). The lines are drawn for ease of viewing.

3). The increase was correlated (P = 0.005) with oxygen concentration (Fig. 4).

From those high values, lactate reduced slowly over time (Fig. 3), with the pattern of recovery varying with the oxygen concentration. At high oxygen concentrations (70–80%, 90–100% and 110–120% saturation) lactate was not significantly different to the control after eight hours re-immersion. In the other treatments, lactate remained high for longer, and in the 30–40% treatment lactate was still significantly higher than the controls after 24 hours re-immersion. The lactate concentration of lobsters in the 10–20% treatment remained very high.

TABLE 3.

The results of the ANOVAs comparing the hemolymph pH of lobsters (*Panulirus cygnus*) in each oxygen concentration treatment at each measurement time during the 24-h recovery, period. Different letters denote significantly different results.

Oxygen Concentration (%)	Recovery Time (h)					
	0	1	2	4	8	24
110–120	a	bc	abc	a	c	b
90–100	a	c	bc	a	c	a
70–80	a	bc	c	b	a	a
50–60	a	a	ab	a	b	a
30–40	a	b	ab	a	b	a
10–20	a	a	a	b	b	N/A

N/A - the lobsters in this treatment did not survive for 24 h.

Hemolymph glucose increased during the 30-minute disturbance period from 0.35 ± 0.06 mmol L^{-1} to 0.44 ± 0.06 mmol L^{-1}, but it was not a significant increase (Fig. 5). After 1-hour re-immersion, the glucose concentration in all treatments was significantly higher than the control. The largest increases were measured in the low oxygen saturation treatments (Table 5). In general, the high glucose concentrations were maintained for between two and four hours, most were not significantly different to the controls after eight hours re-immersion. Lobsters in the 110–120% and 50–60% treatments still had significantly higher concentrations than the controls after eight hours re-immersion, however the concentrations were not significantly different to those in all other treatments except for the 10–20% treatment.

DISCUSSION

Biochemical disturbances induced in *P. cygnus* by emersion and handling included a large decrease in the hemolymph pH and an increase in the hemolymph lactate concentration. Re-immersion

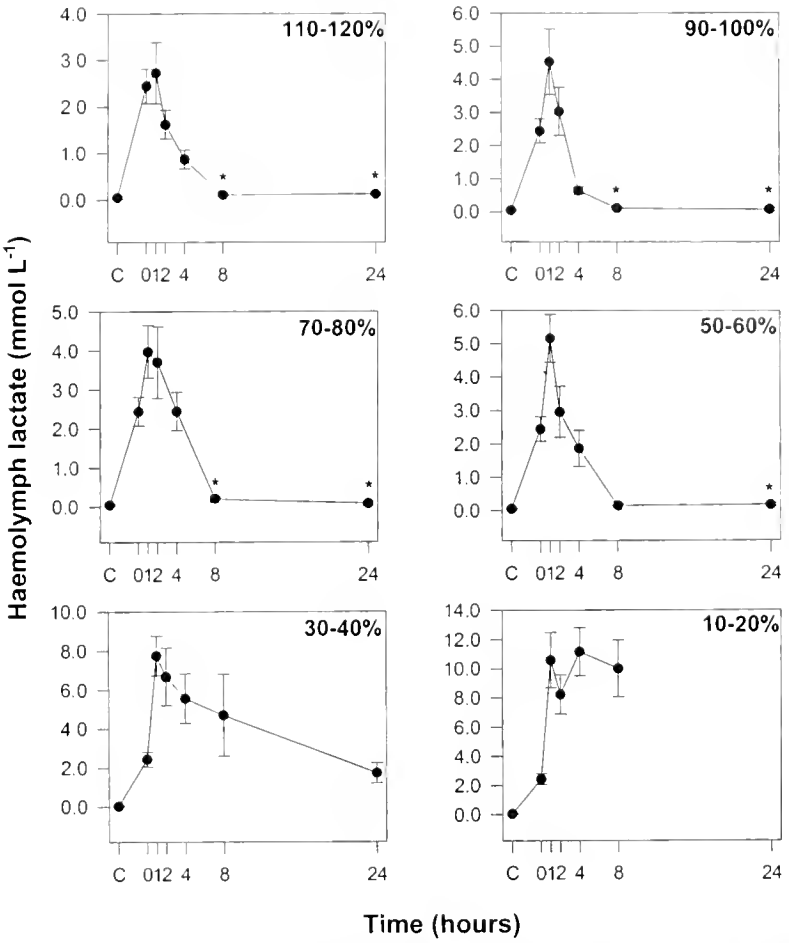

Figure. 3. Hemolymph lactate concentration (mmol L^{-1})(mean ± SE) of the western rock lobster, *Panulirus cygnus*, over a 24-hour period during "recovery" from disturbance (n = 6 to n = 12). N/A - the lobsters in this treatment did not survive for 24 h.

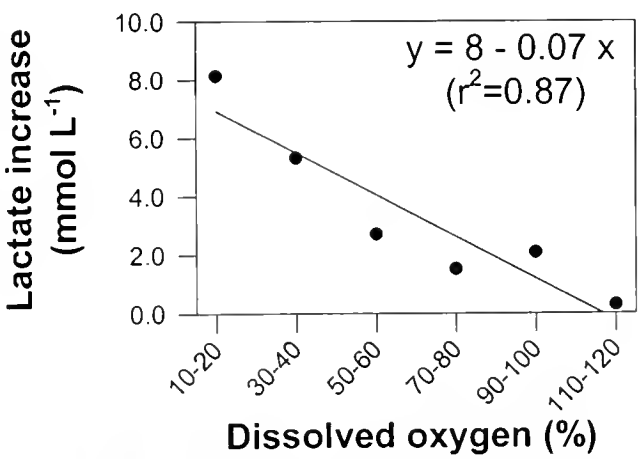

Figure. 4. Increase in hemolymph lactate (mmol L^{-1})(●) during the first hour of recovery after re-immersion of lobsters, *Panulirus cygnus*, in water at different dissolved oxygen concentrations. The equation describes the relationship.

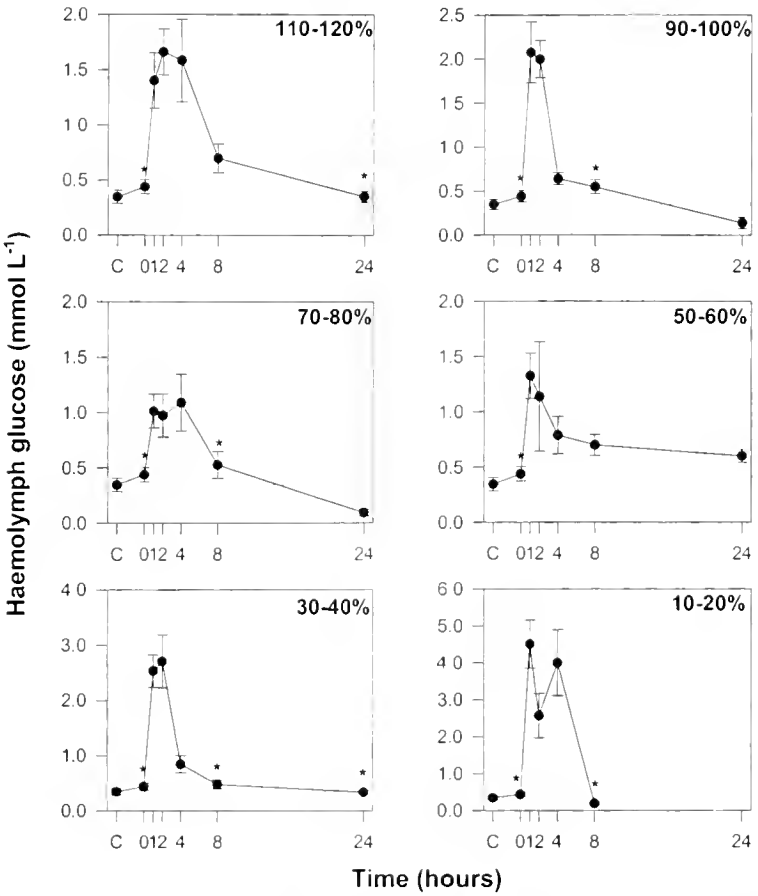

Figure. 5. Hemolymph glucose concentrations (mmol L^{-1}) (mean ± SE) of the western rock lobster, *Panulirus cygnus*, over a 24-hour period during "recovery" from disturbance (n = 6 to n = 12). The lobsters were disturbed (emersed and handled) for 30 minutes prior to re-immersion in water containing different concentrations of dissolved oxygen. Dotted line: control hemolymph glucose concentration (n = 12). *, not significantly different to the control (C). The lines are drawn for ease of viewing.

centrations of 70–80% saturation or above maximizing the rate of recovery. At those concentrations stress indicators returned to normal levels within eight hours of re-immersion. Oxygen concentrations <60% saturation, which are commonly measured in holding tanks (Crear & Forteath 1997), slowed the rate of recovery.

The aerobic response of *P. cygnus* during recovery follows a typical Type V pattern. That is, the oxygen consumed during recovery exceeds the predicted aerobic oxygen deficit (Herreid II 1980). If it is assumed that the emersed lobsters can take up ~50% of the oxygen that they are able to take up in water (Whiteley & Taylor 1990, Waldron 1991), and that they were fully active over the 30 minute period of disturbance, then the maximum oxygen deficit would be ~0.06 mg O_2 g^{-1}. In fact, this is less than one-quarter of the oxygen debt incurred at high concentrations dissolved oxygen. Suggested uses for the excess oxygen include: (1) metabolising anaerobic end products; (2) re-establishing resting oxygen concentrations in body tissues; (3) replenishing high-energy phosphate reserves; and (4) meeting energy costs associated with increased branchial chamber ventilation and hemolymph circulation (Herreid 1980, Head & Baldwin 1986).

TABLE 5.

The results of the ANOVAs comparing the haemolymph glucose concentration (mmol L^{-1}) of lobsters (*Panulirus cygnus*) in each oxygen saturation treatment at each measurement time during the 24-hour recovery period. Different letters denote significantly different results.

Oxygen Saturation (%)	Recovery Time (h)					
	0	1	2	4	8	24
110–120	a	cd	bcd	b	a	b
90–100	a	bc	abc	b	a	c
70–80	a	d	d	b	a	c
50–60	a	cd	cd	b	a	a
30–40	a	b	a	b	ab	b
10–20	a	a	ab	a	b	N/A

N/A the lobsters in this treatment did not survive for 24 h.

The recovery period at high concentrations of dissolved oxygen (70–80% and above) was similar to that observed previously for *P. cygnus* (Crear & Forteath 2001) and for other crustaceans (McMahon et al. 1979, Waldron 1991). However, the recovery period increased as the oxygen concentration decreased, indicating that the lobsters either (a) were not accessing sufficient oxygen to repay the debt as quickly or (b) were increasing the size of the debt as a result of the processes involved in repaying the debt or (c) both. Thus:

(a) The ability of lobsters to take up oxygen upon re-immersion was dependent on the dissolved oxygen concentration. The critical oxygen tension (P_c) in this study (63.1%) was close to the 62.8% calculated by Crear and

Forteath (2001) for active *P. cygnus* at 23 C. The aerobic scope for activity (the amount of oxygen available to the lobsters above normal maintenance requirements) increased as oxygen concentrations increased up to P_c. Lobsters with a large aerobic scope for activity should be able to shorten the time required to repay a similar oxygen debt. Lobsters in the 30–40% treatment were very limited in the amount of oxygen they were able to extract from the water (≈50% of maximum VO_2). Therefore, total oxygen consumption over the first eight hours of re-immersion in that treatment was ≈25% lower than in the higher oxygen treatments. Access to oxygen was a major problem with these lobsters and would explain (at least partly) the slow recovery rates. Similarly, in response to an injection of lactate *C. maenas* increased VO_2, but the response was lesser, and lasted longer, under hypoxic conditions than under normoxic conditions (De Wachter et al. 1997). Those authors suggested that the response was due to the larger aerobic scope at the higher oxygen concentration.

(b) The total amount of oxygen consumed in the 50–60% treatment during the first eight hours of re-immersion was ~30% higher than in the treatments with higher oxygen concentrations. Although the oxygen consumed was high, they still had not repaid the oxygen debt, which indicates that there were increased energetic costs associated with recovery at that oxygen concentration. The increased energetic costs could arise from: (i) the increased cost of branchial chamber ventilation and hemolymph circulation when diffusion of oxygen from the external medium to the hemolymph via an oxygen gradient would be minimal and/or, (ii) an increased reliance on anaerobic respiration, together with production of lactate and associated energetic costs of resynthesizing the substrate or oxidizing lactate further to carbon dioxide (Gäde et al. 1986).

The pH response of crustaceans to the combination of stressors used in this study (emersion, exercise and handling) has not often been investigated. Spanoghe (1997) recorded a similar large decrease (0.7 pH units) in *P. cygnus* after one hour of emersion and handling. A pH change of that magnitude must be considered a large physiological perturbation (Vermeer 1987). Return to control pH values after re-immersion was optimized at oxygen concentrations of 90–100% and above. The time taken was similar to that of other crustaceans (McDonald et al. 1979, Waldron 1991, Whiteley & Taylor 1992).

Schmitt and Uglow (1997) concluded that CO_2 accumulation was mainly responsible for emersion-induced acidosis in *Nephrops norvegicus*, despite the presence of high concentrations of lactate. Recovery of acid-base status during re-immersion in this study varied with the oxygen concentration, and also appears not to be determined by lactate concentrations. Lobsters at low oxygen concentrations (50–60%, 30–40% and 10–20%) had large increases in lactate during the first hour of re-immersion, while their hemolymph pH showed significant increases. Taylor and Wheatly (1981) noted that the potential acidosis, which the increase in lactate represents, was overridden by a respiratory alkalosis due to the washout of CO_2 during the period of hyperventilation. In the present study, oxygen consumption upon re-immersion was relatively low at lower oxygen concentrations, so less CO_2 would have been produced, whilst high ventilation and perfusion activities would have promoted the excretion of CO_2 across the gills. These two factors may have resulted in the large pH increase after one hour of re-immersion into poorly oxygenated water. At the higher dissolved oxygen concentrations, the hemolymph pH remained low after one hour of recovery, even though the hemolymph lactate was lowest in these lobsters. The high V_{O_2} of lobsters held at the higher oxygen concentrations may result in CO_2 concentrations remaining elevated in the hemolymph, thus helping to maintain a low pH during the initial stages of recovery. Elimination of accumulated CO_2 is usually rapid, however, Waldron (1991) found that hemolymph CO_2 partial pressure remained significantly elevated for two hours during re-immersion after a period of emersion and exercise in *J. edwardsii*.

A hemolymph alkalosis was measured during the recovery period in lobsters subjected to 70–80% oxygen saturation or lower. Crustaceans generally hyperventilate in response to hypoxia, leading to hypocapnic alkalosis due to an increase in the rate of excretion of CO_2 (Hagerman & Uglow 1985). The pH of *A. leptodactylus* increased by 0.16 units with exposure to 30% oxygen saturation (Sinha and Dejours 1980). In other studies in which the pH of crustaceans undergoing recovery has risen (Truchot 1975; Whiteley and Taylor 1992; Spanoghe 1997), the oxygen concentrations in the recovery tanks may have been lower than optimal.

Resting concentrations of hemolymph lactate (0.05 mmol L^{-1}) were similar to those measured in other decapod crustaceans (0.14 mmol L^{-1} for *J. edwardsii*, Waldron 1991; 0.14 mmol L^{-1} for *Ranina ranina*, Paterson et al. 1994; 0.09 mmol L^{-1} for *Carcinus maenas*, De Wachter et al. 1997). There have been few reports on the hemolymph lactate concentrations of crustaceans that have been emersed and exercised. However, in *J. edwardsii* after a short period of exercise followed by one hour of emersion lactate increased by ~1.0 mmol L^{-1} (Waldron 1991) and in *P. cygnus* lactate increased by 2 mmol L^{-1} after 40 minutes of emersion and disturbance (Spanoghe 1997); increases which were similar to this study. The slow rate of lactate removal from the hemolymph indicates that *P. cygnus*, like many other crustaceans, lack the means for rapid removal of lactate (McDonald et al. 1979, Ellington 1983, Waldron 1991). Return to normal concentrations was optimized at oxygen concentrations of 50–60% and above.

The increase in hemolymph lactate concentration of *P. cygnus* indicates that it was unable to maintain an adequate supply of oxygen to the tissues during the period of disturbance and needed to rely, at least partially, on anaerobic metabolism to supply its energy requirements (Spicer et al. 1990). The rise in lactate concentration after re-immersion has also been noted in other crustaceans subjected to periods of exercise and/or emersion (McDonald et al. 1979, Taylor & Wheatly 1981, Whiteley and Taylor 1992). Increased hemolymph lactate concentrations after re-immersion may be due to the release of lactate previously stored in the tissues during the disturbance period, as suggested by Taylor and Wheatly (1981) and Waldron (1991). In *C. destructor* it appears that a steady state between tail muscle and hemolymph lactate pools is reached quite rapidly (Head & Baldwin 1986), hence lactate release may not fully explain the increased concentrations. Another possible explanation is that lactate production may have increased on re-immersion due to a high energy demand requiring a contribution from both aerobic and anaerobic metabolism (Head & Baldwin 1986, Gruschczyk & Kamp 1990, Whiteley & Taylor 1992). Onnen and Zebe (1983) suggested that the use of anaerobic metabolism during the recovery process might ensure that the muscle function is restored as soon as possible. In this study, the relative increase in the lactate concentration during the first hour was dependent on the dissolved oxygen concentration in the water. When oxygen could not fully fuel the aerobic portion of the energy requirements of recovery, the shortfall was made up via anaerobic

metabolism. This suggests that the observed increase in hemolymph lactate is probably due to the continued use of anaerobic energy sources after re-immersion, rather than the release of sequestered lactate. During recovery in the 110–120% treatment, metabolism appears to be mainly aerobic as shown by the absence of further accumulation of lactate.

Hemolymph glucose concentrations of control lobsters are similar to those measured in other studies: 0.2–0.3 mmol L^{-1} for *Nephrops norvegicus* (Spicer et al. 1990, Schmitt & Uglow 1997); 0.2–0.4 mmol L^{-1} for *P. cygnus* (Tod & Spanoghe 1997). The maximum concentrations of hemolymph glucose measured in this study (1.0 to 4.5 mmol L^{-1}) also covered the range of maximum concentrations measured by those researchers. As has been noted in other studies (Onnen & Zebe 1983, Gruschczyk & Kamp 1990, Tod & Spanoghe 1997), there was a marked hyperglycemia in the hemolymph of *P. cygnus* one hour after re-immersion. In this study, the hyperglycaemia was more severe in lobsters subjected to low dissolved oxygen concentrations, suggesting that more energy substrate was required because the lobsters were relying more on anaerobic metabolism. When aerobic mechanisms of energy production are impaired, in order to provide a given amount of energy, more glucose must undergo anaerobic glycolysis (Storey & Storey 1990), as anaerobic glycolysis produces only about 1/20th of the energy produced via aerobic glycolysis (Eckert et al. 1988). During recovery in this study, anaerobic glycolysis (as indicated by lactate concentration), increases as oxygen saturation decreases. Therefore, the increases in hemolymph glucose concentrations would be expected.

The time period of recovery from hyperglycaemia has not been well studied, but it was similar to that for *P. cygnus* in Spanoghe's (1997) study, and to that recorded for *Palaemon serratus* and *P. elegans* after a period of emersion (Taylor & Spicer 1987). Speed of recovery to normal glucose concentrations was optimized at oxygen concentrations of 70–80% and above.

In conclusion, oxygen has a considerable effect on the recovery response of *P. cygnus*. The duration and the effectiveness of the recovery process are of great functional importance. Recovery from anaerobic metabolism should be sufficiently rapid and complete for the organism to cope with further periods of stress. For example, in the case of muscles powering escape responses, this process of recovery must be sufficient to allow the organism to evade predators (Ellington 1983). Using speed of recovery as the criteria for evaluating the effectiveness of oxygen concentrations, the results show that a minimum of 70–80% saturation is required, with some indication that higher concentrations (including slight supersaturation) may offer some benefits.

ABSTRACT Because in the premolt stage *L. stylirostris* should produce glycogen to prepare chitin synthesis, the present paper was directed to answer the following questions: (a) Could an absence of dietary carbohydrates (CHO) enhance the gluconeogenesis pathway in premolt shrimp, following the trend in species of carnivorous fish? (b) In premoulting shrimp is it necessary to force the glyconeogenic pathway through intensive feeding or is a two meal/day feeding schedule enough? (c) Is the CHO metabolism adaptation affected by the age of shrimp? and (d) are the same mechanisms working in moult stage C and D? A comparison with shrimp fed the same diets and in stage C has been done to determine the effect of the molt stage and dietary CHO levels in glycogen accumulation of this shrimp species. Results obtained showed that in stage D shrimp the gluconeogenic pathway was enhanced, both in an intensive or in a two meal/day feeding schedule, independently of the age of the shrimp. The accumulation of glycogen to support both chitin synthesis and metabolic glucose is proposed as an explanation. Comparing the results obtained in the present paper with that of *L. stylirostris* juveniles published earlier, it is possible to observe that both in 12 hour fasting and during glycemia, the glycogen concentration in stage C shrimp was opposite of that observed in stage D shrimp. These results show that the intensity of the gluconeogenesis pathway changes with the molting stage, being of more importance in the premolt stage (D) than during the intermoult stage (C).

KEY WORDS: carbohydrate metabolism, gluconeogenesis, Digestive gland, blue shrimp *Litopenaeus stylirostris*, molt stage, juveniles, glycogen

INTRODUCTION

Carbohydrate metabolism is complex in Crustaceans. Although metabolic aspects are identified, the whole aspect of regulation is still uncertain (Shiau & Peng 1992, Ceccaldi 1998). In recent papers *L. stylirostris* juveniles showed a limited capacity to use dietary carbohydrates. A saturation curve was measured in glycogen levels and α-amylase activity against dietary carbohydrate levels (CHO). Maximum values of both the metabolic indexes were obtained in shrimp fed diets containing 21% CHO and that was recommended as a maximum shrimp dietary CHO level for *L. stylirostris* culture (Rosas et al. 2001a).

This limitation may be a consequence of a metabolic adaptation to use protein as a primary source of energy. Protein is the main reserve substrate in shrimp, and can be converted to carbohydrates following the gluconeogenic pathway (Campbell 1991). Recently we had observed that the gluconeogenic pathway is at constant rate in several shrimp species. In *L. stylirostris* (Rosas et al. 2000), *L. setiferus* (Rosas et al. 2001b), and *L. vannamei* (Taboada et al. 2001) a relatively high glycogen level (4.3 mg/g, 4.9 mg/g, and 10.1 mg/g) was observed in shrimp fed during 40 days with 1% of dietary CHO levels, indicating the importance of gluconeogenesis. The internal ammonia, ammonia excretion, glutamate dehydrogenase activity (GDH), and osmotic pressure measurements showed that the route of protein metabolism was purposed as a donor of amino acids to obtain glycogen. Gluconeogenesis in crustaceans is a biosynthetic pathway for *de novo* synthesis of glucose from lactate or alanine in an inter-tissue cooperation pathway. According to Lallier and Walsh (1991), the flux of lactate and alanine is oriented to glucose biosynthesis intensively, giving at the digestive gland a gluconeogenic role. An elevation in phosphoenolpyruvate carboxykinase (PEPCK), the regulatory enzyme of gluconeogenesis pathway, was related to the increase of gluconeogenesis pathway in *L. vannamei* fed with 1% dietary CHO (Rosas et al. 2001a). Similar results were seen in *Chasmagnathus granulata* crabs (Oliveira & Da Silva 1997) and in *Callinectes sapidus* (Lallier & Walsh 1991). Those results emphasized the gluconeogenetic role of the digestive gland.

Shrimp, like other decapods, have an organic reserve cycle which show modifications. During the molt cycle, glycogen reserves are actively accumulated from stage Do, preparing the animal for chitin synthesis (Renaud 1949). If the shrimp can synthesize glycogen during stage C, the mechanisms associated with glycogen synthesis in stage Do to D1‴should be overstimulated, producing important changes at the tissue level.

Hepatosomatic index (or Digestive gland index; DGI) has been used as an index in CHO metabolism of the digestive gland, because there is a direct relation between glycogen concentration and digestive gland weight in shrimp (Gibson & Barker 1979, Jayaprakas & Sambhu 1998, Ramos et al. 1996, Sambhu & Jayaprakas 1997). According to Renaud (1949), this DGI should be changed according to the molt stage, showing the changes in CHO metabolism associated with storage reserves for molting. To date, CHO metabolism has been studied in stage C shrimp but we do not know if the gluconeogenic pathway in shrimp works in the same way when it needs more CHO to be prepared for chitin synthesis.

In carnivorous fish, (cod fish) fed without dietary CHO, it was observed that the hepatosomatic index was higher than that observed in fish fed with 25–50% dietary CHO (Hemmre et al. 1990). This was interpreted as an adaptation of cod to increase the gluconeogenic pathway to store CHO reserves. Is this type of mechanism working in the same form in shrimp? There is no information in penaeid shrimp.

Glycemia produced by meal has been reported in several shrimp species. Shiau and Peng (1992) reported that glycemia in *P. monodon* was produced two to five hours after feeding and depended on the CHO type. Similar results were reported by Abdel Rahman (1996) in *P. japonicus*, by Rosas et al. (1995a) in *L. setiferus* adult males, by Lignot et al. (1999) in *L. stylirostris* and by Cousin (1995) and Rosas et al (2001a) in *L. vannamei*. Once the food is digested in the gut, chime and fine particles are digested in the lumen and absorbed by diffusion by the inner portion of the digestive gland tubules, initiating the accumulation of reserves. After absorption, glucose passed through the digestive gland (DG) wall to the blood and glycogen is stored (Al-Mohanna & Nott 1987). This mechanism should be modified when shrimp are fed without CHO. In first instance it should be fast enough to transform the dietary protein into glycogen during intermoult period without CHO supply. In *L. setiferus* and *L. vannamei* intermoult (stage C) shrimp fed without CHO, it was observed that during glycemia, glycogen is accumulated two to three hours after feeding, evidencing that without dietary CHO glycemia is a fast process (Rosas et al. 2001b). In premolt shrimp (stage D), this mechanism could be enhanced.

Most experiments done with nutrients tend to test a gradient of a nutrient (protein for example) against another (carbohydrate CHO for example). Then interpretation leads to a double sense whether one considers one nutrient in relation with another. To alleviate that problem, diets can be formulated and distributed on a pair-feeding approach, which can maintain protein constant with and without dietary CHO level. With this method it is possible to maintain the shrimp in a constant feeding schedule causing a permanent glycemia (Cousin 1995, Rosas et al. 2000a).

Because in the premolt stage, shrimp should produce glycogen to prepare for chitin synthesis, the present paper was directed to answer the following questions: (a) Could an absence of dietary CHO enhance the gluconeogenesis pathway in premolt shrimp, following the trend in species of carnivorous fish? (b) In premolting shrimp is it necessary to force the glyconeogenic pathway through an intensive feeding approach or is it enough to use a two meal/day feeding schedule? and (c) Are the CHO metabolism adaptations affected by the age of shrimp? A comparison with shrimp fed with the same diets and in stage C (Rosas et al. 2000) was done to determine the effect of the molt stage and dietary CHO levels in glycogen accumulation of this shrimp species.

Digestive gland index, digestive gland glycogen concentration, and blood glucose levels of juveniles and adults of *L. stylirostris* were evaluated. Two experiments were done at the "Centre Océanologique du Pacifique" (Ifremer) located in Tahiti. In the first experiment the effect of dietary CHO levels on digestive gland glycogen, DGI, and blood glucose after glycemia produced by feeding in premolt shrimp were evaluated. The second experiment determined the effect of age of premolt shrimp on DGI and digestive gland glycogen after intensive feeding and in the absence of dietary CHO.

MATERIALS AND METHODS

Animals

First Experiment

One hundred shrimp (9.45 ± 0.15 g wet weight) were reared for 15 to 18 days at a density of 8 shrimp/72-L (8 shrimp/m^2) tank in a flow through sea water system (1 L/min; salinity of 35‰). In such system seawater was renewed 15 times a day. The light dark photoperiod was 12 h/12 h and water temperature was 28 + 1°C. The shrimp were fed *ad libitum* three times a day (0800, 1200, and 2000). Uneaten food particles were removed each day after each meal. Four tanks were randomly assigned to each carbohydrate level.

Second Experiment

Fifty juvenile shrimp (7.8 ± 0.5 g wet weight) and fifty pre adult shrimp (19.4 ± 1.9 g wet weight) were reared in 72-L dark tanks at a density of 6 shrimp/tank (6 shrimp/m^2) in a flow through sea water system (35‰) and with a water exchange of 45 L/h. The light dark photoperiod was 12 h/12 h and water temperature was 28 ± 1°C. The amount of the diet fed was calculated to have the same amount of protein ingested and feeding frequency was adjusted accordingly. High CHO (HCHO) level diet was given seven times a day at the same intervals in a quantity of 0.07 g/animal per time. This time allow let shrimp time to consume 100% of the food. The low CHO (LCHO) level was adjusted to represent 60% of the amount ingested by animals receiving the HCHO dietary level. To do that, one out of two feed distributions was omitted in the LCHO level. Shrimp were fed 12 days for juveniles and 8 days for pre adults. This period was considered to have each sample population receiving a given experimental diet and to have animals in intermolt stage comprised between Do and D1‴.

Diets

First Experiment

The juveniles were fed formulated semi purified diets prepared with different levels of carbohydrates: 1%, 10%, 21%, and 33%. The ingredients composition of the experimental diets are presented in Table 1. The experimental diets were prepared by thoroughly mixing the dry ingredients with oil and then adding water until a stiff dough resulted. The dough was then passed through a mincer with a die, and the resulting spaghetti-like strings were air dried at 60 C. After drying, the diets were broken up, sieved to a convenient pellet size, and stored at −4°C.

Second Experiment

Experimental diets were formulated as described in Table 1. These diets were prepared similarly to the diets used in the first experiment.

Moulting Stages

In both experiments, the molt stage was observed at the uropodae with a binocular (×50) for the largest characteristics and the microscope (×400) for the smallest characteristics, following the criteria published by Drach and Tchenigovtzeff (1967) for decapods and Aquacop (1973) for shrimp. In the present paper only shrimp in stages Do to D1‴ were used.

Physiological Measurements

Digestive Gland Index

At the end of the feeding period of both experiments, shrimp were sacrificed and the digestive gland index was measured (DGI). The digestive gland weight was obtained by using a Mettler balance (±0.001 g) to get wet weight of the digestive gland over total live weight.

d Disodium phosphate and monopotassium phosphate in equal amount.

e 23/35/15 Kj for protein, lipid and carbohydrate, respectively (Cousin, 1995).

Glucose and Glycogen Measurements

In the first experiment, glycogen content of the digestive gland was determined from a sample of five shrimp from each treatment, at time 0 (after 12 h fasting) and 1, 2, 3, 6 and 7 hours after feeding. Glycemia was identified when the glycogen level of the digestive gland reached its maximum level after feeding. In the second experiment glycogen content of the digestive gland was determined from six shrimp from each treatment and size population after 12-hour fasting. After weighing, the digestive gland was preserved in liquid nitrogen for further glycogen determinations.

In both experiments glycogen was extracted following the method reported by Dubois et al. (1956). Each mid gut gland was first homogenized in trichloroacetic acid (TCA, 5%) for 2 min at 16,000 rpm, and centrifuged (3000 rpm for 5 min). This procedure was done twice. One mL of TCA was pipetted into a tube and mixed with 5 volumes of 95% ethanol. The tubes were then placed in an oven at 37–40°C for 3 h. After precipitation, the tubes were centrifuged at 3000 rpm for 15 min. The precipitate containing the glycogen was dissolved by addition of 0.5 mL of boiling water and 5 mL of concentrated sulfuric acid and phenol (5%). The contents of the tubes were transferred to a colorimeter tube and read at 490 nm in a microplate spectrophotometer.

Statistical Analysis

The effect of different dietary levels of carbohydrate on the glucose content of digestive gland glycogen was analyzed separately using ANOVA. Homogeneity of variances was verified with the Cochran's test. Means for each treatment were compared using Duncan's multiple range test only after ANOVA indicated significant differences among all the dietary treatments. The arc sin transformation was used before testing the difference between percentage data (Zar 1974)

RESULTS

First Experiment

Both preprandial and during glycemia, the DGI changed in terms of CHO levels (Fig. 1). In preprandial condition, the highest DGI (4.8%) was in shrimp acclimated with 1% CHO dietary level ($P < 0.05$). The lowest DGI level (3.0%) was in shrimp fed with 33% CHO. During glycemia, the DGI increased between 22% and 57% with the lower values in shrimp fed with 33% CHO level (DGI = 3.9%) and the highest in shrimp fed with 1% CHO level (DGI = 7.3%) ($P < 0.05$). There were no statistical differences between DGI of shrimp fed with 10% and 21% CHO levels (mean value of DGI = 4.6%) (Fig. 1).

A higher preprandial digestive gland glycogen concentration was measured in shrimp acclimated at a 1% dietary CHO level (8.8 mg/g) in comparison to that obtained in the rest of CHO level (mean value of 6.3 mg/g) (Fig. 2; $P < 0.05$). A similar behavior was observed during glycemia with high glycogen concentration in shrimp fed 1% CHO levels (15.3 mg/g). A mean value of 9.7 mg/g

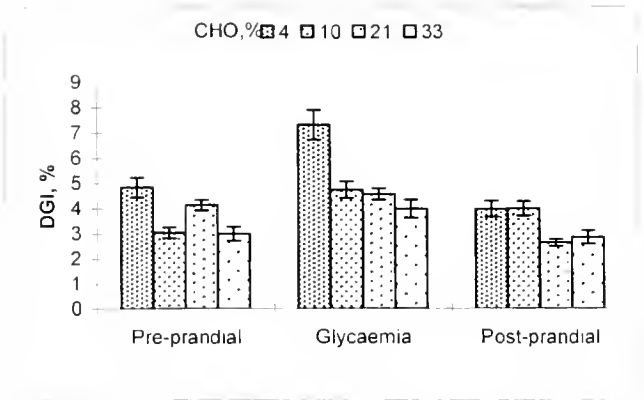

Figure 1. Wet digestive gland index (%) of *Litopenaeus stylirostris* juveniles after feeding with different carbohydrates (CHO) levels. Mean ± S.E. First Experiment.

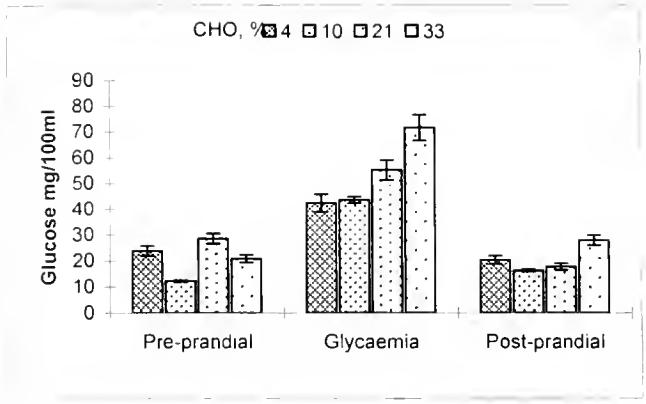

Figure 3. Glucose hemolymph levels (mg/100 ml) of *Litopenaeus stylirostris* juveniles after feeding with different carbohydrates (CHO) levels. Mean ± S.E. First Experiment.

of digestive glycogen was recorded in shrimp fed with 10%, 21%, and 33% CHO (Fig. 2).

Preprandial hemolymph levels did not show any relation to dietary CHO levels (Fig. 3). The highest values were recorded in shrimp fed 1% and 21% CHO (mean value of 25 mg/100 mL) and the lowest in shrimp fed with 10% CHO (12.3 mg/100 mL). An intermediate value (20.8 mg/100 mL) was obtained in shrimp fed with 33% CHO. After a meal, glucose hemolymph level increased between 50% and 241%, with lower values in shrimp fed with 1% and 10% CHO (mean value of 42.5 mg/100 mL) and the highest in shrimp fed with 33% CHO (71 mg/100 mL) (Fig. 3) ($P < 0.05$). An intermediate value of glucose hemolymph concentration (55 mg/100 mL) was obtained in shrimp fed with 21% CHO.

Second Experiment

The highest DGI was measured in shrimp fed without dietary CHO when shrimp were fed in an intensive feeding schedule: both juveniles and pre adults (Fig. 4). In juveniles, the highest DGI (0% CHO) was 21% higher than that observed in shrimp fed with 40% CHO ($P < 0.05$). In pre adults the highest DGI (0% CHO) was 9% higher than that measured in shrimp fed with 40% CHO ($P < 0.05$). In both diets, the DGI changed with age; juveniles were between 94% and 119% DGI higher than that observed in pre adult shrimp (Fig. 4; $P < 0.05$).

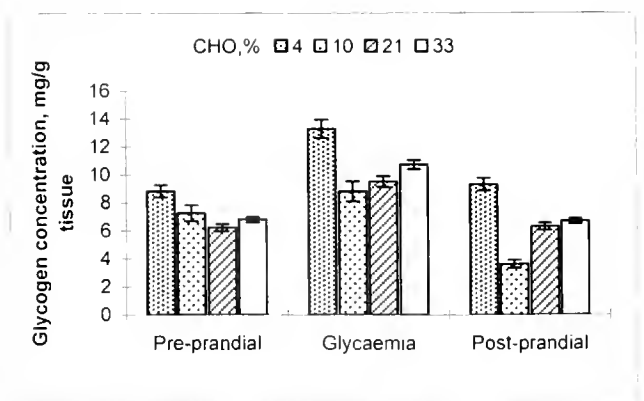

Figure 2. Digestive gland glycogen (mg/g tissue) of *Litopenaeus stylirostris* juveniles after feeding with different carbohydrates (CHO) levels. Mean ± S.E. First Experiment.

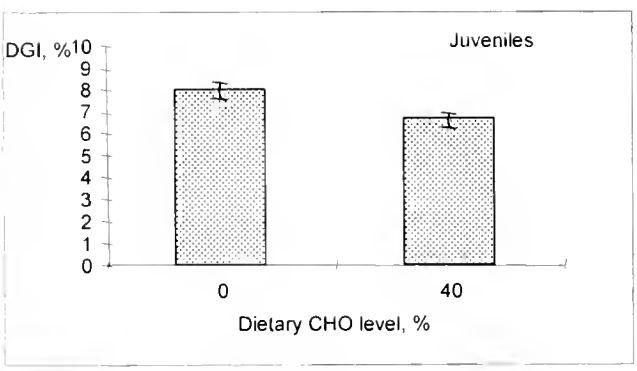
No statistical differences were observed in digestive gland glycogen of shrimp fed with high and low dietary CHO levels (Fig. 5).

DISCUSSION

The digestive gland index (DGI) of *L. stylirostris* premolt shrimp is affected by CHO level in diet. According to many workers, the digestive gland (DG) is the principal storage organ of glycogen and represents more than 80% of reserves and is the site for gluconeogenesis (Gibson & Barker 1979, Lallier & Walsh 1991, Oliveira & Da Silva 1997). The changes of weight in DG can be attributed to the glycogen storage. Part of dietary glucose will be converted to glycogen affecting the weight. Three and five



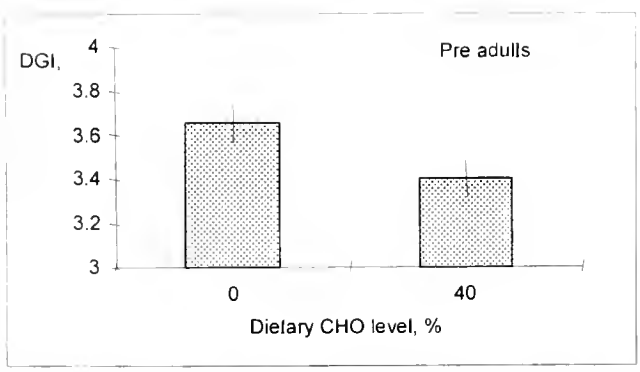


Figure 4. Wet digestive gland index (%) of *Litopenaeus stylirostris* pre adults fed with 0 and 40% dietary carbohydrates (CHO) levels. Mean ± S.E. Second Experiment.

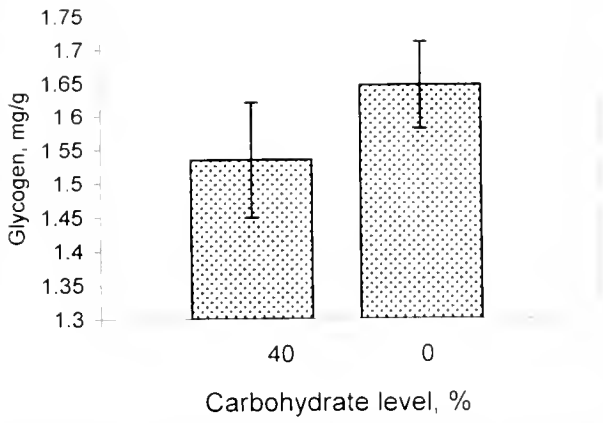

Figure 5. Digestive gland glycogen (mg/g wet tissue) of *Litopenaeus stylirostris* pre adults fed with 0 and 40% dietary carbohydrates (CHO) levels. Mean ± S.E. Second Experiment.

hours after a meal, a peak in DGI and glycogen concentration was measured in *L. vannamei* juveniles (Cousin 1995) and in *L. setiferus* adult males (Rosas et al. 1995b).

Both experiments in the present study, juveniles and pre adults showed the highest DGI and glycogen concentration were obtained when shrimp were fed with low dietary CHO level or without dietary CHO, showing that without dietary CHO the gluconeogenic pathway was induced (Fig. 1, Fig. 4). This induction means that *L. stylirostris* is well adapted to use protein as a source of metabolic energy and to make glycogen. According to Cuzon et al. (1998), *L. stylirostris* is omnivorous-carnivorous, justifying its adaptation to process protein-rich diets.

During the molting process (stages Do to D1‴), crustaceans not only accumulate glycogen but also triglycerides and proteins in the DG in preparation for chitin synthesis (Santos & Keller 1993). During this time, the hexokinase activity is increased to accumulate glycogen, reducing the pentose pathway in preparation of chitin synthesis and the demands for energy (1.4 kJ representing about 25% of the energy accumulated along the intermoult cycle), which is provided through the glycolysis pathway. The highest levels of DGI and DG glycogen observed in shrimp fed without CHO reflect the amount of glycogen that the shrimp needs to support both the chitin synthesis and the production of metabolic glucose. This has been observed in other shrimp species in stage C of molt (Rosas et al. 2000, Rosas et al. 2001a, Rosas et al. 2001b). In contrast, in shrimp fed with CHO rich diets a high gluconeogenesis is not necessary because shrimp have enough CHO from the diet to satisfy the chitin synthesis and glucose for energetic demands producing, in consequence, the lowest levels of the DGI and DG glycogen.

In a recent paper (Rosas et al. 2001a), we demonstrated that *L. vannamei* can convert protein to glycogen by a gluconeogenic pathway when fed with 1% dietary CHO. In that study we measured a high phosphoenolpyruvate carboxykinase (PEPCK) activity indicating that the gluconeogenic pathway is induced to produce glycogen and glucose. This activation allowed maintenance of a relatively high circulating glucose of 0.34 mg/mL in hemolymph in comparison to that observed in shrimp fed with 30% dietary CHO (0.45 mg/mL). A similar pattern has been observed in *Chasmagnatus granulata* crabs (Oliveira & Da Silva 1997) in which the production of glucose from ^{14}C alanine was demonstrated.

This type of strategy is not exclusive to shrimp. In a carnivorous fish such as cod, the hepatosomatic index (HIS) followed a similar pattern as with *L. stylirostris* with a HSI of 6.5% when fish were fed without CHO and 5.3% when fed with 40% starch. These results suggest that cod are well adapted to obtain CHO from protein, knowing this fish in the wild does not have dietary CHO (Hemre et al. 1990).

The present results can be related to the adaptation of shrimp to respond to the protein and carbohydrate variations in wild also. Donaldson (1976) demonstrated that, depending on the season of the year; proteins are the most abundant molecules in benthic ecosystems ranging between 46% to 72% in comparison to 1% to 2.5% of CHO. That observation suggest that wild shrimp are obligated to adapt to synthesize CHO according to environmental protein fluctuations, adjusting their metabolism to be dependent on the abundance of proteins more than CHO.

During glycemia, the highest DGI and glycogen levels were measured in *L. stylirostris* fed without dietary CHO, both in an intensive feeding schedule and after a single meal. Between juveniles (Fig. 1, Fig. 4), the highest DGI was observed in shrimp fed intensively, indicating that in this type of feeding regimen the gluconeogenesis pathway can be forced to produce more glycogen

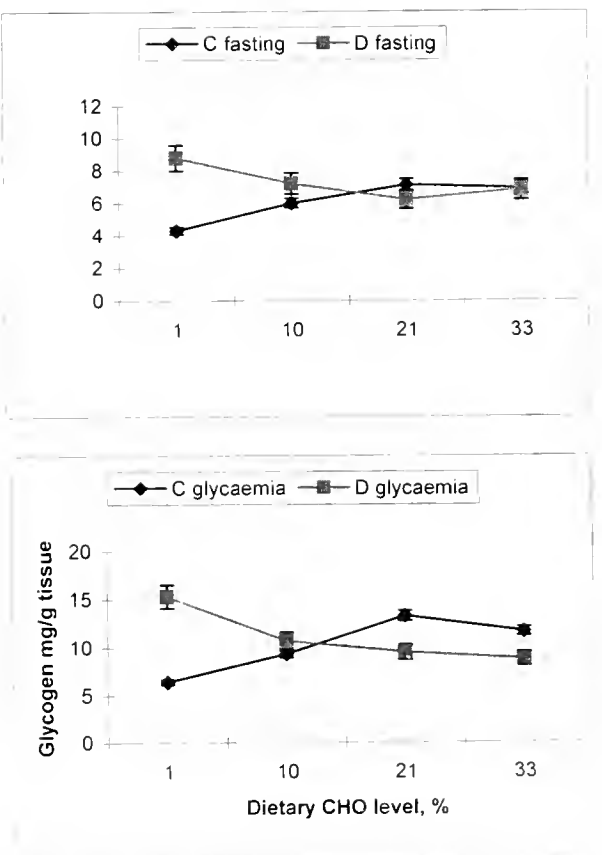

Figure 6. Digestive gland glycogen (mg/g wet tissue) of *Litopenaeus stylirostris* fed with different CHO levels and with shrimp 12 h fasting and during glycaemia. Data for stage C from Rosas et al., (2000). Mean ± S.E.

than that observed only after a meal. In the intensive feeding trial, shrimp were fed every hour starting from 0800 to 1630, which represented around seven meals a day. This rhythm of feeding procured a constant high blood glucose level and the highest glycogen level in the DG. Feeding has been shown to decrease hemolymph hyperglycemic hormone (CHH) levels activating the glycogen synthesis, resulting in increase of glycogen content in different tissues (Santos & Keller 1993). If high glucose remains for a long time in the blood after feeding, the control of CHH could be reduced maintaining the glycogen synthesis for a long time and evidencing the poor regulation of CHO metabolism by shrimp. Similar results were shown by Cousin (1995) in a previous study in which he observed the postprandial effect of different starches in *L. vannamei* juveniles. All these results suggest that the gluconeogenesis process is fast and independent of the molt stage. In previous work, we observed in *L. stylirostris* fed without CHO that the peak of glycogen after a single meal is between two to three hours (Rosas et al. 2000). In this present study made with shrimp in stage D, glycemia was reached two hours after feeding when shrimp were fed after 12 hours fasting. These results could indicate that the molting stage changes the intensity of the process but not its rate. The use of labeled CHO in diets could help confirm this hypothesis.

The age of shrimp does not affect the intensity of gluconeogenesis in shrimp fed without CHO. As in juveniles, pre adults had the highest DGI and DG glycogen levels when they were fed without CHO. The shrimp culture industry had demonstrated that shrimp broodstock are more carnivorous than juveniles, because at that age the shrimp needs more protein and lipids for sexual maturation (Bray & Lawrence 1992). For this reason the gluconeogenesis in the adult phase could be more important than in juveniles.

Comparing the results obtained in the present paper with those for *L. stylirostris* juveniles and published in Rosas et al. (2000), it is possible to observe that both in 12 hour fasting and during glycemia, the glycogen concentration in stage C shrimp was the inverse of that measured in stage D shrimp (Fig. 6). These results show that the intensity of gluconeogenesis pathway changes with the molting stage, being more important in the pre molt stage (D) than during the inter molt stage (C). In the same paper, a significant induction of α-amylase and α-glucosidase activities related to an increase in dietary CHO levels were measured in *L. stylirostris* juveniles indicating that in stage C the dietary CHO affected directly the CHO metabolism.

During growth, the molting process requires the shrimp to make dramatic physiological, behavioral, and metabolic changes to satisfy energetic and structural demands (Bauer 1996, Carvalho & Phan 1998, Charmantier et al. 1994). To satisfy energetic demands, *L. stylirostris*, as other shrimp species, is well adapted to use protein independently of the dietary CHO. The DG changes observed in the present study confirm that assumption and the limited ability of this shrimp species to use dietary CHO, mainly when the glycogen demands are enhanced by the molting stage.

ABSTRACT Variations in the concentrations of ascorbic acid (AA) and tocopherols in association with the gonadal development of the freshwater prawn *Macrobrachium rosenbergii* were investigated in females captured in the Mae Klong River, Thailand. Mean ovarian AA levels ranged from 210 to 540 μg/g dry weight (dw) and were at least 11-fold higher than midgut gland (MG) levels. Variations in ovarian AA levels are believed to be related to the biosynthesis of steroid hormones, the formation of collagen, and the deposition of egg yolk compounds. α-Tocopherol (α-T) was the predominant form of vitamin E in prawn tissues and eggs. The level of α-T in the MG was constant, whereas in the ovaries, it ranged from 143 to 425 μg/g dw. The incorporation of α-T into the ovary was highly correlated ($r^2 = 0.87$) to ovarian lipid levels, which probably reflects the role of this vitamin as a major antioxidant agent. The present results provide further evidence of the essentiality of these vitamins in crustacean reproduction.

KEY WORDS: ascorbic acid, tocopherols, *Macrobrachium rosenbergii*, wild, reproduction, nutrition

INTRODUCTION

Although in the last two decades much progress has been achieved in the understanding of vitamin metabolism in crustaceans (Conklin 1997), knowledge concerning the role of vitamins in crustacean reproduction is still limited (Harrison 1990, Harrison 1997). As a result, most information on vitamin functions and requirements are adopted from literature on fish and other vertebrates, rather than being derived from studies with crustaceans (Harrison 1990).

Vitamin E (tocopherol) and vitamin C (ascorbic acid [AA]) are considered essential dietary components for crustaceans (Conklin 1997). The biological activity of vitamin E is widely accepted to be at least partially related to its antioxidant properties, as it reacts rapidly with organic free radicals that may damage membrane-bound polyunsaturated fatty acids (PUFA) (Burton & Trabor 1990). Vitamin E and C are known to act synergistically, with vitamin E reacting with lipid peroxy radicals donating a hydrogen atom and forming a vitamin E radical, which is then regenerated by AA (Packer et al. 1979). The importance of vitamin E for fish reproduction has long been recognised (Watanabe & Takashima 1977, Watanabe et al. 1985), but has only been recently demonstrated in crustaceans (Cahu et al. 1991, Alava et al. 1993b, Cahu et al. 1995).

Aside from its role in the recycling of vitamin E, AA also participates in the enzymatic processes involved in the formation of collagen (Barnes 1975; Hunter et al. 1979) and in the biosynthesis of steroid hormones (Hilton et al. 1979; Seymour 1981). Although the need for AA in diets for fish broodstock has been well established (Watanabe & Takashima 1977, Sandnes et al. 1984, Soliman et al. 1986, Waagbo et al. 1989, Dabrowski 1991, Blom & Dabrowski 1995), the essentiality of AA in crustacean reproduction was initially inferred from a study evidencing its variation in the ovary of *Palaemon serratus* Pennant (Guary et al. 1975). More recent studies on penaeid shrimps have confirmed its importance in crustacean reproduction (Alava et al. 1993a, Alava et al. 1993b, Cahu et al. 1995).

Under rearing conditions, feed regimes for the freshwater prawn *Macrobrachium rosenbergii* (de Man) range from fresh food to formulated feed, and thus vitamin rations may vary considerably. As no information is available on the status of vitamin E and C in adult prawn tissues during maturation, it is not possible yet to establish criteria for evaluating the ovarian status of these vitamins or to recommend modifications in the dietary vitamin content so as to optimize broodstock performance and offspring quality. With this in mind, this paper aims to present baseline data on the concentrations of AA and tocopherols in the midgut gland, ovary, and eggs of wild *M. rosenbergii* throughout sexual maturation, and it discusses the possible roles that these vitamins may have in the reproduction of this species.

MATERIAL AND METHODS

Live mature *M. rosenbergii* females were obtained from fishermen in the Mae Klong River, Amphur Muang, Province of Samut Songkhram, Thailand. Captures were made in single collections on July and September 1998. After capture, female prawns were grouped in five stages of gonadal development, according to the size, colour, and aspect of the ovary (Chang & Shih 1995), i.e., (I) no ovarian tissue is visible, which is characteristic of both nondeveloped and spent females; (II) the ovary has a small yellow-colored spot near the posterior part of the carapace; (III) the ovarian tissue turns orange and is visible from the posterior part of the carapace to the area just in front of the epigastric tooth; (IV) the ovarian tissues have grown and extended to the area of the epigastric tooth; and (V) the ovarian tissues have extended to the anterior part of the carapace. Females in all five stages of gonadal development were sampled on July and September.

Females were then blotted dry and were individually measured (total length from the tip of the rostrum to the end of the telson) and weighed (to the nearest 0.1 g). The ovary and midgut gland were quickly dissected, weighed, and immediately frozen at −20°C. Grayish, eyed-eggs were also sampled and conserved in a

TABLE 1.

Weight, total length, ovary weight, and midgut gland weight of wild *M. rosenbergii* females at different stages of gonadal development. Each value is the mean of four separate prawn samples analyzed individually, except for stages I and II where tissues of three prawns were pooled. Within rows, values with different superscript letters indicate significant differences ($P < 0.05$).

	Stage of Gonadal Development				
	I	II	III	IV	V
Prawn weight (g)	33.4 ± 12.4	34.3 ± 10.1	41.4 ± 12.5	36.7 ± 11.6	38.8 ± 10.2
Prawn length (cm)	14.4 ± 1.1	14.7 ± 1.4	15.2 ± 1.9	15.4 ± 1.7	15.5 ± 1.4
Midgut gland weight (g)	1.37 ± 0.50	1.38 ± 0.39	1.79 ± 0.54	1.53 ± 0.48	1.73 ± 0.45
Ovary weight (g)	0.17 ± 0.06^{c}	0.53 ± 0.15^{c}	1.16 ± 0.35^{bc}	1.62 ± 0.51^{ab}	2.33 ± 0.60^{a}

similar manner. The gonado-somatic index (GSI) and midgut somatic index (MSI) were calculated as the percentage of gonad and midgut gland to total body weight, respectively. All samples were conditioned in a Styrofoam box with dry ice and were transported by air to Belgium. Samples for AA and tocopherol analysis were then maintained at –80°C and –20°C until analysis, respectively. The content of AA of the samples was determined according to Nelis et al. (1997), while α-tocopherol (α-T), γ-tocopherol (γ-T), and δ-tocopherol (δ-T) levels were estimated following Huo et al. (1999). Tissue samples from the same wild *M. rosenbergii* females were utilized in a parallel study describing the variation of total lipids, lipid classes, and fatty acids (Cavalli et al. 2001).

Statistical analysis of the data was undertaken with one-way analysis of variance (ANOVA) followed by Tukey's honest significant difference (HSD) test. An alpha level of 0.05 was used to identify significant differences. Correlations were determined using linear regression analysis. A minimum of three replicates for each tissue and eggs were analyzed. When tissues of one individual were insufficient for analysis, tissues were pooled from 2 to 4 individuals. This was especially true for the early stages of gonadal development. Results are presented as means ± SD.

RESULTS

Prawn weight, total length, and midgut gland weight presented no significant differences between the various stages of maturation, but ovarian weight tended to increase, especially after stage III (Table 1). Changes in MSI and GSI during maturation are shown in Figure 1. MSI was constant irrespective of maturation stage, whereas GSI presented a significant increase from stages I to V.

Figure 2 summarizes the data on the concentrations of AA in the midgut gland (MG) and ovary throughout maturation. The content of AA in the MG was constant in the early stages of maturation, but decreased significantly from stage III (mean of 24.9 μg/g dw) to stage V (12.8 μg/g dw). In the ovary, the AA concentrations were stable at around 540 μg/g dw at stages I and II, but declined significantly between stages II to IV. At stage V, ovarian AA levels increased significantly to 370 μg/g dw. Within the same stage of gonadal development, mean AA levels were 11- to 29-fold higher in the ovary than in the MG. Eggs contained 128.2 ± 28.3 μg AA/g dw (Table 3).

The main form of tocopherol present in the MG, ovary, and eggs was α-T (Tables 2 and 3). In the MG, there were no significant differences in tocopherol content, as the variations were large. The content of α-T in the ovary increased significantly during the initial stages of gonadal development (from stages I to III), and decreased afterwards. The levels of γ-T were not significantly different at any given stage of maturation, and δ-T levels were below the detection limit during the initial stages of maturation. The mean content of α- and γ-T in the eggs was 324.7 and 22.8 μg/g dw, respectively (Table 3). No δ-T was detected in the eggs.

Linear regression analysis of the total lipid content in the ovary (data from Cavalli et al. 2001) against the concentration of α-T produced a correlation coefficient (r^2) equal to 0.87 (Fig. 3). Correlations between ovarian total lipids and γ- and δ-T levels were not significant.

DISCUSSION

Although only a limited number of studies report AA levels in crustaceans, it is well documented that tissue levels vary with season, ontogenetic development, dietary intake, moulting, and reproductive cycles (Guary et al. 1975, Magarelli & Colvin 1978, Coglianese & Neff 1981, Merchie et al. 1995). In fish, several

authors (Seymour 1981, Sandnes & Braekman 1981, Dabrowski 1991) have demonstrated that the levels of AA in the ovaries change during the reproductive cycle. Sandnes and Braekman (1981) showed a rise in ovarian AA concentration during ovarian growth followed by a decrease in the final stages prior to spawning, and they discussed whether this variation could be related with sex steroid synthesis. Guary et al. (1975) also postulated that the decrease in AA levels in the maturing ovary of *P. serratus* could be connected to steroidogenesis. In the present study, the decline of AA levels in the ovary between stages II to IV coincides with an active phase of ecdysteroid hormone accumulation in the maturing ovaries of *M. rosenbergii* (Wilder et al. 1991). Furthermore, significant levels of cholesterol, the chief precursor of steroid hormones (Kanazawa & Teshima 1971), were present in the ovary of *M. rosenbergii* throughout maturation (Cavalli et al. 2001). These findings reflect a possible demand for AA by the hydroxylating reactions needed for steroidogenesis in the ovarian follicle cells, and they agree with results revealing the possibility of endogenous production of steroid hormones in crustaceans (Kanazawa & Teshima 1971, Shih & Liao 1998).

The decrease in the ovarian AA content between stages II and IV could also be linked to the biosynthesis of collagen, as the hydroxylation reaction necessary for the synthesis of this fibrous protein requires the presence of AA at adequate levels (Hunter et al. 1979). In this respect, the concentration of total ovarian protein has been shown to increase linearly along with GSI in *M. rosenbergii* (Lee & Chang 1997).

Guary et al. (1975) suggested that the formation of egg yolk compounds, such as polysaccharides and glycogen, also require considerable amounts of AA and therefore could be an additional cause for the decrease in ovarian AA levels, particularly at the final stages of gonadal development. Although the possibility that these metabolic processes consume some AA cannot be ruled out, the observation that the levels of AA in the ovary of *M. rosenbergii* increased from stage IV to V suggests that the deposition of AA into the ovary at the final stages of maturation occurs at a much higher rate than its catabolism.

The raise in ovarian AA content in the final stages of maturation may be related to an increased requirement in the egg at a later stage of life (Hilton et al. 1979). Indeed, it was found in various fishes (Hilton et al. 1979, Dabrowski 1991, Blom & Dabrowski 1995) and crustaceans (Guary et al. 1975, Coglianese & Neff 1981, Alava et al. 1993a) that AA levels in the ovaries are usually higher than in other tissues. Similarly, in the present study, the ovary of *M. rosenbergii* contained significantly more AA than the MG. Sandnes et al. (1984) and Soliman et al. (1986) confirmed that an important share of the broodstock dietary AA intake is transferred to the oocytes where it is stored for use during embryogenesis and larval development. This clearly indicates a preferential transfer of reserve AA to the embryos, which is particularly important in *M. rosenbergii* since the embryos and early larvae are totally dependent on the yolk reserves for normal organogenesis and physiological functioning (Harrison 1990). Several authors have shown that the viability of fish eggs (Sandnes et al. 1984, Soliman et al. 1986, Waagbo et al. 1989) and shrimp eggs (Cahu et al. 1995) was directly related to their AA content. The improvement in egg viability with increased AA levels was attributed to the protection of membrane-bound lipids against oxidation and by the action of this vitamin in the synthesis of stable forms of collagen (Cahu et al. 1995), as suggested for fish (Waagbo et al. 1989).

In an earlier study, De Caluwé et al. (1995) collected *M. rosenbergii* eggs 2 days after fertilization and found that mean AA levels in the eggs varied between 210 and 382 μg/g dw. The upper limit of this range agrees well with the ovarian AA content at the final stages of maturation in the present study (around 370 μg/g dw), but is relatively higher than the 128 μg AA/g dw found in the eggs. However, as the eggs sampled here were "eyed" and gray colored, and were thus at the final stages of embryonic development (New & Singholka 1982), this suggests that the developing

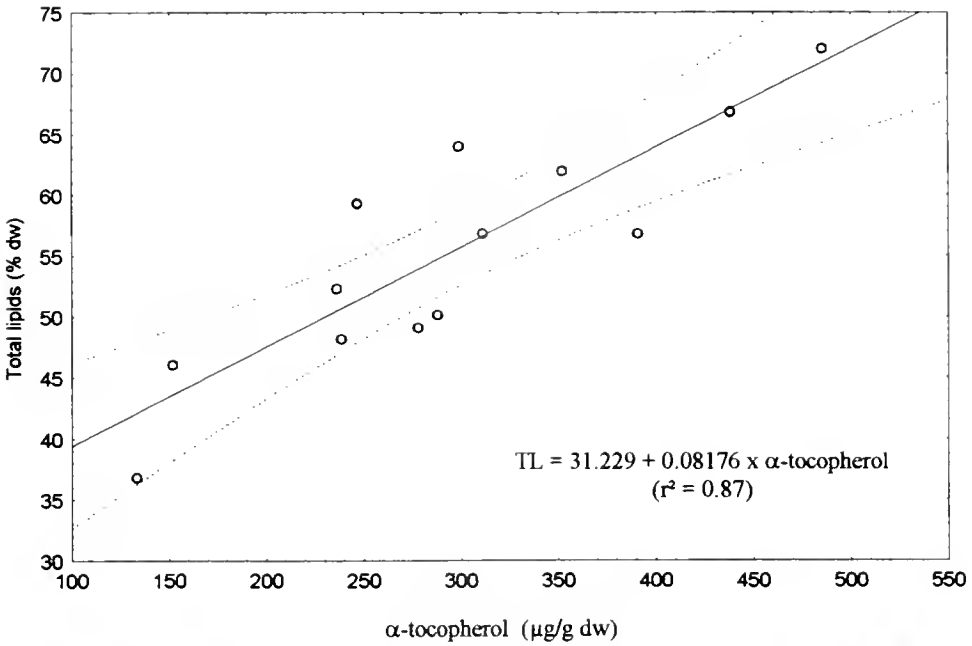

Figure 3. Linear regression analysis between the total lipids (TL) and the contents of α-T in the ovary of wild *M. rosenbergii* females.

embryos possibly consumed AA. Moreover, the fact that newly hatched, nonfeeding larvae of *M. rosenbergii* contained from 149 to 265 μg AA/g dw (Cavalli et al., 2000) further indicates that AA was indeed consumed by the developing embryo. This possibility is also supported by the results of Sato et al. (1987) who demonstrated a continuous decrease in AA content of rainbow trout eggs during embryonic development. Conversely, Guary and Guary (1975) reported that the eggs of *P. serratus* and *Cancer pagurus* (L.) seemed able to synthesize AA during the early stages of embryonic development, and hence, AA contents after spawning were found to be similar to those just before hatching. However, from a metabolic standpoint, it seems unlikely that a female shrimp would accumulate considerable amounts of AA into its gonad (Guary et al., 1975) if the eggs were able to biosynthesize it during the early stages of embryonic development. Therefore, it remains to be confirmed whether the biosynthesis of AA occurs during the embryonic development of crustaceans.

Watanabe et al. (1985) reported that vitamin E, together with lipids, was easily incorporated into red sea bream eggs. According to the present results, the incorporation of α-T into the ovary of *M. rosenbergii* was highly correlated to ovarian lipid levels. This finding is in agreement with the antioxidative role of this fat-soluble vitamin, which requires its close association with lipids, particularly membrane-bound PUFA. Therefore, it is possible that to fulfill its vitamin E requirements, reproductive *M. rosenbergii* females would depend more on the dietary intake than on body reserves, as was hypothesized for lipids (Cavalli et al. 2001). Nevertheless, the contribution of MG and muscle reserves may also be of some importance. Data from the studies of Castillo et al. (1989) and Alava et al. (1993b) indicate that α-T might have been transferred from these tissues to the eggs of *P. indicus* and *P. japonicus*, respectively. It is still unclear whether this is also true for *M. rosenbergii*.

De Caluwé et al. (1995) found that *M. rosenbergii* eggs had from 711 to 1,287 μg α-T/g dw. These concentrations are much higher than those found in the present study, and they suggest a comparatively lower dietary intake of vitamin E under natural conditions. In fact, the rate of incorporation of vitamin E into the eggs of *P. indicus* and *M. rosenbergii* was shown to increase with dietary levels of α-TA (Cahu et al. 1991, De Caluwé et al. 1995). *M. rosenbergii* females fed a diet containing 223 μg α-TA/g dw produced eggs with an average of 711μg α-T/g dw, while the content of α-T in the eggs almost doubled to 1,287 μg/g dw when dietary α-TA levels were increased to 2,025 μg/g dw.

In summary, the present study provides further evidence of the importance of AA and tocopherols in the reproduction of crustaceans, and consequently suggests that feeding a diet deficient in either vitamin C or E could virtually impair broodstock performance and offspring viability. More research is necessary to determine optimal dietary levels for crustacean broodstock.

ACKNOWLEDGMENTS

We wish to thank Mr. Nopadol Phuwapanish (Department of Fisheries, Thailand) for his help in the collection and sampling of the prawns, and Dr. Greet Merchie (INVE Aquaculture, Thailand) for the transportation of the samples. We also thank Mathieu Wille for critically reading the manuscript. The assistance of Petra Rigole in the analytical work is also greatly appreciated. This research was funded in part under grant No. 200796/96-8 from the Brazilian Council for Science and Technology (CNPq).

GROWTH AND GAMETOGENIC CYCLE OF THE CRESTED OYSTER, *OSTREA EQUESTRIS* (SAY, 1834), IN COASTAL GEORGIA

RANDAL L. WALKER AND ALAN J. POWER

Marine Extension Service, Shellfish Aquaculture Laboratory, University of Georgia, 20 Ocean Science Circle, Savannah, Georgia 31411-1011

ABSTRACT Crested oysters, *Ostrea equestris* (Say, 1834), were collected from the mouth of the Savannah River on December 2, 1998 and transferred to pearl nets suspended from the main dock at the Skidaway Institute of Oceanography on the Skidaway River. To determine the reproductive cycle and growth of oysters, 50 oysters were collected monthly, measured for shell length, and a gonadal sample was taken for histological analysis. Oysters grew from a mean size of 18.8 mm in January 1999 to 28 mm by November 1999—a rate of 0.9 mm per month. Of 574 oysters sectioned for histological examination, males dominated the population (49.5%), with only 3.5% being females, 4.5% were indeterminate and 42.5% being hermaphrodites. Crested oysters were reproductively active year around in Georgia with spawning and spent oysters occurring in most months. In males, spawning and spent stages ranged from 23.7% of the oysters in January to 86.4% in August, while females in these stages ranged from 10.7% in February to 77.8% in August. Brooding larvae were found in the histological samples between April and October. Spawning of crested oysters in Georgia occurs year round with major spawning starting in February and continuing into fall.

KEY WORDS: crested oyster, *Ostrea equestris*, growth, gametogenesis, hermaphroditism

INTRODUCTION

The crested oyster, *Ostrea equestris* (Say 1834), occurs from North Carolina to both coasts of Florida, throughout the Gulf of Mexico and to the West Indies (Abbott 1974). Externally, the crested oyster appears similar to the eastern oyster, *Crassostrea virginica* (Gmelin 1791), but can be distinguished from it by a single row of denticles along the inner lateral margin of the upper valve with corresponding depressions on the lower valve (Galtsoff & Merrill 1962). The crested oyster is a high saline organism occurring in estuarine areas greater than 20 ppt to oceanic conditions (Galtsoff & Merrill 1962). It grows to 72 mm in length in the Gulf of Mexico (Gunter 1951) and to 82 mm on the Atlantic coast (Galtsoff & Merrill 1962). Crested oysters do not form beds like *C. virginica* (Galtsoff & Merrill 1962). *O. equestris* will replace *C. virginica* on beds when salinity increases to 30 ppt (Parker 1960). Hoese (1960) observed in Texas at the end of a drought, an *O. equestris - Brachidontes exustus* community was replaced by a *C. virginica - B. recurvus* community.

Although there have been several reports published on the biology of *O. equestris* from the Gulf of Mexico region (Gunter 1951, Menzel 1955, Parker 1960, Hoese 1960) and one distributional study on the Atlantic coast (Galtsoff & Merrill 1962), studies on life history traits for Atlantic coast populations are absent. This study describes the growth and gametogenic cycle of the crested oyster in the coastal waters of Georgia.

MATERIALS AND METHODS

Crested oysters were collected by the R/V Georgia Bulldog while trawling with a 3 m conch try net at the mouth of the Savannah River (32°02′42″ X 80°50′21″) 1998 December 2. The sampling depth was 6 m and the sediment was dominated by shelly material. Surface salinity was 24 ppt. Oysters attached to relic *C. virginica* shells were returned to the laboratory where 50 non-randomly selected oysters were measured for shell length (i.e., hinge to lip) to the nearest 0.5 mm with Vernier calipers. This initial sample was non-random because large-sized oysters were selected for ease of identification. After measuring each oyster, the internal lateral margin of each oyster shell was examined to ensure identification and a 1cm^2 gonadal sample was removed and preserved in Davidson's solution. Remaining oysters were placed into 12-mm mesh pearl nets and suspended from the main dock at the Skidaway Institute of Oceanography on the Skidaway River.

Each month 50 oysters were randomly gathered, measured for shell length, and a gonadal sample (ca. 1 cm^2) was dissected from each oyster. These oysters were selected by gathering two *C. virginica* shells from the pearl nets with attached crested oysters. Tissues were processed according to procedures outlined in Howard and Smith (1983). Prepared slides of gonadal tissue were examined with a Zeiss Standard 20 microscope (×20), sexed and assigned to a developmental stage as described by Pouvreau et al. (2000). A staging criteria of 0 to 6 was employed for early active (1), activity developing (2), near ripe (3), ripe (4), partially spawned (5), spent (6), and inactive (0).

Water temperatures and river salinity from the Skidaway River were taken from the Marine Extension Service's dock which is adjacent to the Skidaway Institute of Oceanography's dock at 0800 h Monday through Friday.

RESULTS

Monthly mean water temperature and salinity values for the Skidaway River are given in Figure 1. Temperatures ranged from 12.2°C in January 1999 to 30.9°C in August 1999, while river salinity ranged from 23.4 ppt in July 1999 to 29.9 ppt in December 1999. River salinity values were abnormally high especially during spring due to prolonged drought conditions in the southeast and Georgia.

Crested oyster mean size from December 1998 to November 1999 is given in Figure 2. The mean size of oysters in December 1998 (22 mm) was artificially high because larger-sized animals were selected to ensure the correct identification of the animals at the start of the experiment. The January 1999 size (18.8 mm) represents a random mean size. Thus, oysters grew from 18.8 mm in January 1999 to a mean size of 27.8 mm by November 1999—a rate of 0.9 mm per month.

A total of 574 oysters were sexed from December 1998 to November 1999. Indeterminate oysters occurred in every month except March and April and accounted for 26 individuals (4.5%).

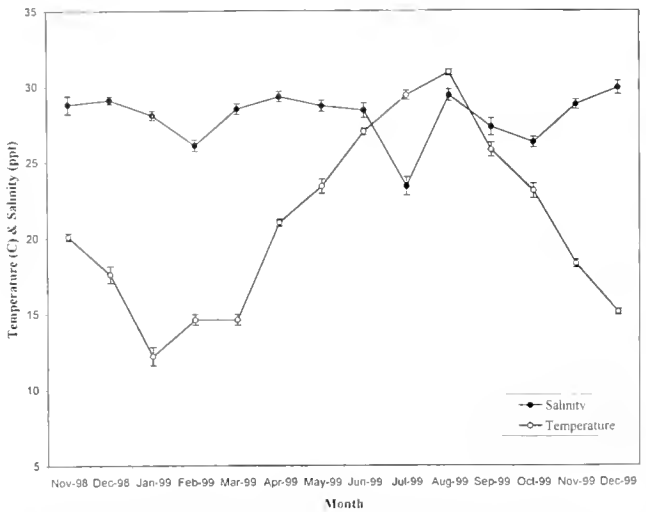

Figure 1. The mean monthly water temperature and salinity of the Skidaway River, Georgia from November 1998 to November 1999 (vertical bars indicate ± 1 standard error from the mean).

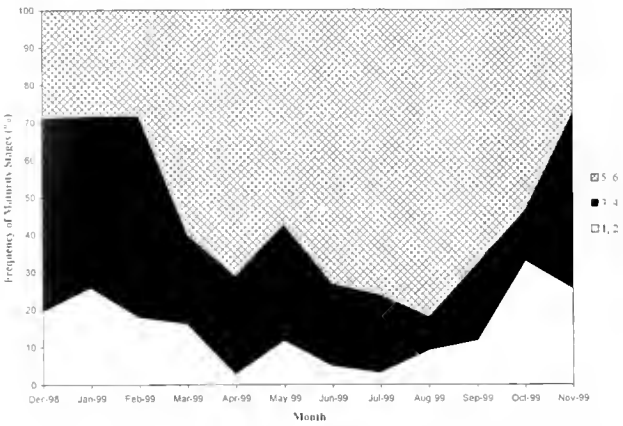

Figure 3. The reproductive phases (early active = 1, activity developing = 2, near ripe = 3, ripe = 4, partially spawned = 5, and spent = 6) of female and male crested oysters, *Ostrea equestris*, from the coastal waters of Georgia between December 1998 and November 1999.

Male individuals occurred every month and totaled 284 individuals (49.5%), while only 20 female oysters (3.5%) occurred. There were no female oysters identified in the December 1998, March 1999, April 1999 and September 1999 samples. Two hundred forty four oysters (42.5%) were hermaphroditic. Hermaphrodites occurred in each month sampled. Brooding larvae in the samples were observed from April to October.

Crested oysters in Georgia were reproductively active year around (Fig. 3). Near ripe and spawning ripe female and male oysters were found in all months. Female and male spawning and spent oysters occurred year-round with these stages dominating from March through December. Male spawning and spent stages ranged from 23.7% of the oysters in January to 86.4% in August, while in females these stages ranged from 10.7% in February to 77.8% in August. Brooding larvae were found in 3.1% of the histological samples occurring in each month from April to October. Spawning appears to be a prolonged event in Georgia starting in February and continuing into fall.

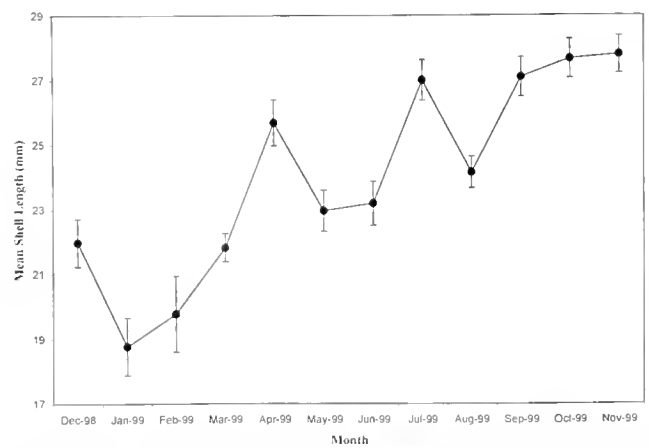

Figure 2. The mean shell length (mm ± standard error) of crested oysters from pearl nets suspended in the Skidaway River, Georgia from December 1998 to November 1999.

DISCUSSION

Within the Ostreidae family, oysters of the genus *Ostrea* are brooding species, whereas, members of the *Crassostrea* genus release their gametes into the water column (Galtsoff 1964). Brooded larvae have been documented in *Ostrea equestris* by Gutsell (1926) and Menzel (1955), and were noted in the present study from histological samples taken between April and October.

Water temperature is a controlling factor in regulating spawning and gametogenesis in marine bivalves (Giese 1959, Sastry 1975). In general spawning periods and gametogensis in marine bivalves start earlier and last longer in southern geographical areas than in northern ones (Eversole 1989, Thompson et al. 1996). *Ostrea equestris* in the subtropical waters of Georgia are reproductively active year around (Fig. 3). Although Menzel (1955) did not follow gametogensis of *O. equestris* on an annual basis, he showed that they continually recruited from the first of May until the first of November indicating prolonged spawning seasoning in Louisiana. Other warm water *Ostrea* species also have long spawning periods and periods of no reproductive inactivity. In Costa Rica, *O. iridescens* was observed spawning 9 out of 14 months, with no reproductive resting stages observed. In New Zealand, *Tiostrea* (=*Ostrea*) *chilensis* spawns year around with peak spawning in late summer-autumn and brood larvae found from July to January (Jeffs 1998, Jeffs & Hickman 2000). In colder waters, *O. chilensis* has one spawning period per year in spring to early summer with brooding lasting only 7 to 8 weeks (Chaparro & Thompson 1998). Likewise, in Argentina *O. puelchana* spawns from December to February; however, no resting stages of reproductive activity were observed with rapid proliferation of ovocytes occurring in March-April (Castro & Mattio 1987). In California *O. lurida* is reproductively active year around, but spawns only during seven months with peak spawning in June and July (Coe 1932a). Spawning in *O. lurida* ceases when water temperatures fall below 16°C (Coe 1932b). In Ireland, *O. edulis* spawns from May to September with minimum reproductive activity from October to February (Wilson & Simons 1985).

Ostrea equestris is a protandric species as are other species of *Ostrea*. Menzel (1955) followed the growth and reproductive cycle of crested oysters from set and observed that 74.4% of the oysters were males and 10% females. Of the remaining oysters, 13% were

indeterminate and only 2.6% were hermaphroditic. In our study, males also dominated (49.5%); however, the percentage of hermaphroditic individuals (42.5%) was much greater than that observed in crested oysters from Louisiana. The crested oysters from Georgia were well beyond the set stage when collected from the Savannah River. Since the crested oyster is protandric as suggested by Menzel (1955), then this could explain the difference in the percent hermaphroditism between populations. The oysters from Louisiana were younger and developing first as males, thus the 74% males, before changing to females or hermaphrodites at a later age or size. Oysters gathered in December 1998 in Georgia already ranged in size from 8.7 mm to 34 mm in shell length, and had probably already past through the initial sex change stage from males to females. In oyster populations, the closer the proximity of one oyster to another, the higher the proportion of males in that population (Burkenroad 1931, Smith 1949, Menzel 1951, Buroker 1983). In the present study, crested oysters were held close together in suspended pearl nets, which may explain the much skewed male to female ratio observed (1:0.07).

Oysters of the genus *Ostrea* have greater occurrences of hermaphrodites than species of *Crassostrea* (Table 1). Galtsoff (1964) stated that oviparous species of oysters (*Crassostrea*) are not usually hermaphroditic, while larviparous species of oysters (*Ostrea*) as a rule change in sexuality (i.e., from an initial male phase followed by alternating female and male phases). *Ostrea edulis* has long been recognized as a protandric species; spat sexually mature as males, spawn, then switch to a female phase. At age one year, these oysters enter a male phase followed again by a female phase.

Most two-year-old oysters are females. In addition, female stages for this species have been observed developing within the gonads as the older gonadal material was releasing sperm (Cole 1942). Mann (1979) observed 29% hermaphroditic individuals in *O. edulis* while finding no hermaphrodites among *C. gigas*. For *O. lurida*, Coe (1932a) found that of 238 oysters 90% was hermaphrodites. Fournier (1992) also found a higher ratio of males to females (3:1) in *O. iridescens* with 2% hermaphroditism. Castro and Mattio (1987) described *O. puelchana* as a rhythmic consecutive hermaphroditic species. In *Tiostrea chilensis* populations, hermaphroditic individuals accounted for 72% and 96% of the oysters sampled in New Zealand (Table 1; Jeffs 1998, Jeffs & Hickman 2000, respectively).

The growth of crested oysters in Georgia was slow—a rate of 0.9 mm per month. The largest oyster observed was 36.1 mm in the September sample, which is half that of the maximum reported size (82 mm in shell length) of the crested oyster (Galtsoff & Merrill 1962). In the Gulf of Mexico region, Menzel (1955) showed that 12 oysters grew from a mean size of 13.1 mm to 29 mm in 9 months—a rate of 1.76 mm per month. The observed slow growth of the Georgia crested oyster is maybe a result of competition for both space and food. Crested oysters were gathered from a natural set in the Savannah River. When oysters were brought to the surface, relic *C. virginica* shells were already densely covered by crested oysters. No attempt to reduce the densities of the shells was made prior to or during the time that the crested oysters were held in pearl nets at the main dock on the Skidaway River. Thus, oysters that were collected in an overcrowded state remained in dense numbers throughout the sampling period. High stocking densities of bivalves result in slower growth rates (Sheldon 1968, Walker 1984, Holliday et al. 1993, Jensen 1993, Adams et al. 1994).

OYSTER REEFS AS FISH HABITAT: OPPORTUNISTIC USE OF RESTORED REEFS BY TRANSIENT FISHES

JULIANA M. HARDING* AND ROGER MANN

Department of Fisheries Science, Virginia Institute of Marine Science, College of William and Mary, P.O. Box 1346, Gloucester Point, Virginia 23063

ABSTRACT Under the Magnuson-Stevenson Fisheries Management Act of 1996, current fisheries management practice is focused on the concept of Essential Fish Habitat (EFH). Application of the EFH concept to estuarine habitats relates directly to ongoing oyster reef restoration efforts. Oyster reef restoration typically creates complex habitat in regions where such habitat is limited or absent. While healthy oyster reefs provide structurally and ecologically complex habitat for many other species from all trophic levels including recreationally and commercially valuable transient finfishes, additional data is required to evaluate oyster reef habitats in the context of essential fish habitat. Patterns of transient fish species richness, abundance, and size-specific habitat use were examined along an estuarine habitat gradient from complex reef habitat through simple sand bottom in the Piankatank River, Virginia. There was no clear delineation of habitat use by transient fishes along this cline of estuarine habitat types (oyster reef to sand bar). Atlantic croaker (*Micropogonias undulatus*), Atlantic menhaden (*Brevoortia tyrannus*), bluefish (*Pomatomus saltatrix*), silver perch (*Bairdiella chrysoura*), spot (*Leiostomus xanthurus*), spotted seatrout (*Cynoscion regalis*), striped bass (*Morone saxatilis*), and weakfish (*Cynoscion nebulosus*) were found in all habitat types examined. In general, the smallest fish were found on the sand bar, the site with the least habitat heterogeneity. As habitat complexity increased along the gradient from oyster shell bar through oyster reef, transient fish size and abundance increased. Opportunistic habitat use by this suite of generalists relates variations in habitat quality as related to habitat-specific productivity and suggests that oyster reefs may be important but not essential habitat for these fishes.

KEY WORDS: habitat use, essential fish habitat, oyster reef, transient fish, Chesapeake Bay

INTRODUCTION

There is growing recognition by government and management agencies of the importance of habitat to maintenance and sustenance of marine fishery species. The Magnuson-Stevens Fishery Conservation and Management Act of 1996 (Public Law 94-265) as amended by the Sustainable Fisheries Act established the concept of Essential Fish Habitat and provided for the management and protection of such habitat under the auspices of the National Marine Fisheries Service (Benaka 1999). Essential Fish Habitat (EFH) was defined as "those waters and substrate necessary for fish for spawning, feeding or growth to maturity". Under the law, "finfish, molluscs, crustaceans, and all other forms of marine animal and plant life other than marine mammals and birds" are protected. While protection of marine habitats is certainly needed, the scale of the Magnuson-Stevens Act, as established by its terminology, renders application of the law on a practical level next to impossible. The Magnuson-Stevens Act provides a means to classify fish habitats as essential (absolutely necessary per Webster's Dictionary 1983) but offers no opportunities to distinguish gradations in fish habitat quality. Functionally, the only habitat absolutely necessary for fish is reasonably clean water.

As restoration efforts in Chesapeake Bay and other estuaries continue to focus on oyster reef reconstruction and rehabilitation, the nature and importance of oyster reefs as habitat (the place where an animal lives sensu Odum 1971) bears further investigation. Oyster reefs, three dimensional structures created and maintained by living oysters (*Crassostrea virginica*), were historically a principal habitat type in shallow portions of estuaries such as Chesapeake Bay. The chronic decline of oyster populations in the 20th century due to a combination of overfishing, disease, and habitat degradation has reduced oyster populations and virtually eliminated natural oyster reef structures in Chesapeake Bay (Hargis 1999). Oyster reefs are ecologically valuable as habitat for oysters as well as a diverse suite of resident benthic fauna (e.g., oysters, barnacles, mussels, polychaetes, crabs, naked gobies (*Gobiosoma bosc*); Wells 1961, Bahr & Lanier 1981, Meyer & Townsend 2000) and recreationally and commercially valuable transient fishes (e.g., striped bass (*Morone saxatilis*), bluefish (Pomatomus saltatrix), Atlantic croaker (*Micropogonias undulatus*), spot (*Leiostomus xanthurus*); Breitburg 1999, Coen et al. 1999, Harding & Mann 1999, Posey et al. 1999).

The ecological function of oyster reef habitats is dependent upon both structural and ecological features inherent in living reef communities, namely the oyster's benthic-pelagic coupling capabilities and the resulting production of hard shell substrate (Coen et al. 1999, Mann 2000, Coen & Luckenbach 2000). Restored oyster reef communities should follow an ecological progression towards climax or stability in numbers and species (Sale 1980) over time. Various measures of reef community development have been proposed including abundance of adult oysters in relation to local (within 1 km) natural (not restored) oyster populations (Harding & Mann 1999) and larval production in relation to adult abundances for primary and secondary trophic levels of reef residents (Harding & Mann 2000).

There is merit in examining the use of restored oyster reef habitat by transient finfish particularly in relation to local non-reef habitats. Burchmore et al. (1985), Breitburg (1999), and Harding and Mann (1999) describe transient reef fishes as mobile schooling species that are found over a wide range of habitats including reefs. Descriptions of fish species richness in relation to oyster reefs have been made by Wenner et al. (1996), Nestlerode et al. (1998), Coen et al. (1999), Harding and Mann (1999), Minello (1999) and Posey et al. (1999) with the continuing observation that oyster reefs are home to diverse assemblages of transient fishes.

National Marine Fisheries Service guidelines (62 FR 66531, 1997) suggest delineation of EFH in light of four hierarchical information levels (Minello 1999): presence/absence data (Level 1), distribution and abundance (density) information (Level 2), functional relationships between species and habitats: reproduc-

*Corresponding author. E-mail: jharding@vims.edu

tion, growth, and survival (Level 3), and habitat-specific fish production (Level 4). Current designations of habitat as EFH rely on basic information as provided by Level 1 and 2 in the absence of comprehensive data sets addressing information Levels 3 and 4 (Able 1999, Minello 1999). The objectives of this paper are to compare the transient finfish assemblages associated with a gradient of habitats ranging from hard sand bottom to oyster reef within the same estuary and relate the observed patterns of species richness (Level 1), abundance (Level 2), and size-specific habitat use (Level 3) to habitat classifications sensu EFH.

Study Site

Field work was conducted in the Piankatank River, Virginia at three sites (Fig. 1): Palace Bar oyster reef, an oyster shell bar (Ginney Point), and a sand bar (Roane Point). Palace Bar reef is an intertidal oyster reef (210 × 30 m, reef depth range of 0.5 m above mean low water (MLW) to 3 m below MLW) adjacent to the historic Palace Bar oyster grounds. Palace Bar reef was built in 1993 by the Virginia Marine Resources Commission (VMRC) Shellfish Replenishment program as a series of 18 shell mounds centered on and around an east-west centerline 300 m long (Mann et al. 1996). Approximately 70% of the reef (0.63 ha) is composed of oyster shell, while the remaining area (0.27 ha) is crushed clam shell. Palace Bar reef has supported oyster densities similar to those observed on natural (i.e., not constructed) oyster bars in the Piankatank River since 1997 (Harding & Mann 1999, R. Mann, unpublished data). The Ginney Point site is a flat oyster shell bar with a depth range of 2.5–3 m below MLW (Fig. 1). The Roane Point site includes a sand bar (depth range 1.5–2 m below MLW) south and inshore of Palace Bar reef (Fig. 1). Mean tidal range in the Piankatank River is approximately 0.4 m and maximum tidal current at these sites is approximately 0.12 m^{-s} (Chen et al. 1977).

MATERIALS AND METHODS

Transient fishes were sampled using multi-panel experimental gill nets (one 30.5 m × 1.8 m and two 30.5 m × 3.0 m nets all with one 7.6 m panel each of stretch square mesh monofilament of 57.2, 63.5, 73.0, and 76.2 mm) deployed such that the entire water column was sampled (e.g., the smallest net at Roane Point, the shallowest site). Nets were deployed in a straight line parallel to tidal flow at each site. All fishes were removed from the gill nets identified, sacrificed, and measured (total length to the nearest mm) resulting in species-specific presence/absence, abundance, and size estimates across a gradient of habitat types (oyster reef to sand bar).

Transient fishes were collected during 8 thirty-six hour sampling events completed from May through September on the new and full moon (May 22–23, June 5–6, June 19–20, July 2–3, July 17–18, August 4–5, August 18–19, and September 2–3, 1997). Sampling periodicity incorporated complete diurnal and tidal cycles as well as seasonal progression. During each sampling sequence, reef and non-reef sites were sampled at three-hour intervals corresponding to changes in tidal stage for thirty-six consecutive hours. Water temperature and salinity were recorded weekly from May through September 1997 at Ginney Point and Palace Bar reef (Fig. 2).

Data Analyses

Significance levels for all statistical tests were established at $p = 0.05$ *a priori*. Bartlett's test for homogeneity of variance and the Ryan-Joiner test for normality were used prior to parametric analyses. When appropriate, Tukey's tests were used for post-hoc multiple comparisons.

Piankatank River Temperature and Salinity Data

Water temperature and salinity data for Ginney Point and Palace Bar reef were transformed (natural logarithm) to meet the assumptions of homogeneity of variance and normality prior to analyses with ANOVA.

Species-specific Abundance Data

Only the six species that were numerically dominant ($n > 5$ individuals per station for each of the three sites) were used in these analyses. For each species, the number of fish caught per gill net deployment were compared with an ANOVA using site, day of the year, and time of day as factors. Data for bluefish, striped bass, and weakfish met both the assumptions of homogeneity of variance and normality after transformation with the reciprocal transformation (Zar 1996). Data for croaker and spot satisfied the assumptions of homogeneity of variance and normality after logarithmic transformation. Counts for Atlantic menhaden satisfied the assumption of homogeneity of variance with the reciprocal transformation but not normality regardless of the transformation (log + 1, ln + 1, sqrt + 1, reciprocal).

Fish Assemblage-Habitat Relationships

Transient fish species abundance associations were compared across sites using detrended correspondence analysis (DCA). DCA was used as a descriptive tool to characterize the fish assemblages observed at each site on the basis of abundance. DCA ordinations spatially aggregate similar samples and separate dissimilar ones on the basis of species abundances within a sample. All DCA analyses (CANOCO for Windows version 4.0 1998) were detrended with second order polynomials (per ter Braak 1995) to avoid potential loss of gradient information during the detrending procedure (Minchin 1987). Species-samples biplots were made using CANODRAW software (version 3.1, Similauer 1998).

Species-specific Length Data

Total lengths (mm) for the six numerically dominant species were compared with species-specific one-way ANOVAs using site as a factor.

RESULTS

Analyses

Piankatank River Temperature and Salinity Data

Neither water temperatures nor salinity values were significantly different among sampling sites in 1997 (ANOVA, $p < 0.05$). Water temperature and salinity conditions observed in the Piankatank River during 1997 were similar to those observed during 1993–96 (Fig. 2, R. Mann, unpublished data).

Species-specific Abundance Data

Fourteen different transient fish species were observed in gill net collections from Palace Bar reef (Table 1). Ten of these fourteen species were observed at Ginney Point (oyster shell bar) and nine were observed at Roane Point (sand bar). Atlantic croaker, Atlantic menhaden, bluefish, spot, striped bass, and weakfish were the most abundant fish species at all three sites (Table 1).

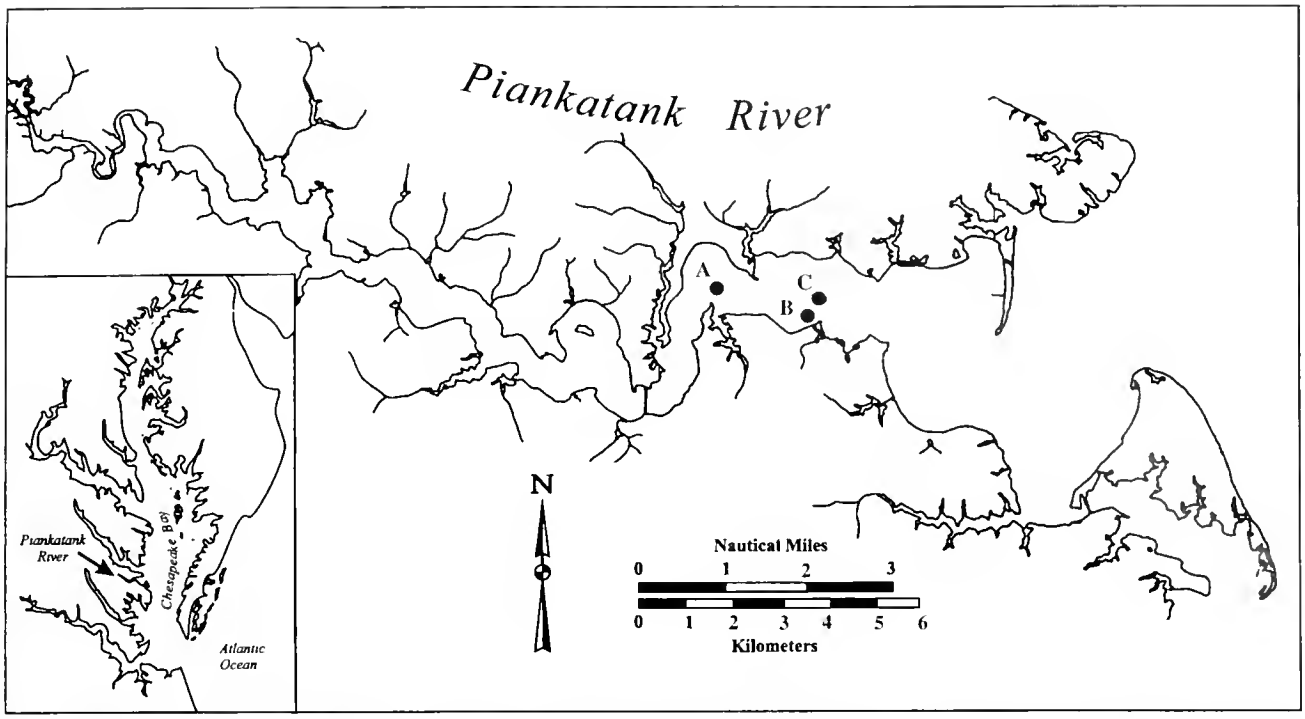

Figure 1. Map of the Piankatank River in relation to the Chesapeake Bay showing sampling locations after Harding and Mann (1999). Palace Bar reef (C), Ginney Point (an oyster shell bar, A) and Roane Point (a sand bar, B) were sampled to provide data for reef vs. non-reef habitat comparisons.

Abundances of Atlantic croaker, Atlantic menhaden, and striped bass were significantly greater at sites with oyster shell substrate (Palace Bar reef and Ginney Point) than at the sand bar site (Roane Point) but there was no significant difference in abundance of these three species between the oyster reef and the oyster bar (Table 2; ANOVA, Tukey test, $p < 0.05$; Figs. 3, 4, and 7). Bluefish were significantly more abundant at the oyster reef than at any other site (Table 2; ANOVA, Tukey test, $p < 0.05$). Spot were significantly more abundant at the oyster bar than at either the oyster reef or the sand bar (Table 2; ANOVA, Tukey test, $p < 0.05$). Weakfish abundance was low relative to the other species and similar across all three sites (Table 2; ANOVA, Tukey's test, $p < 0.05$).

In general, fish abundance increased at night across all sites. Atlantic croaker, bluefish, and spot were significantly more abundant from dusk to dawn (2000–0800) than during the day (Figs. 3, 5, 6; ANOVA, Tukey's test, $p < 0.05$). Striped bass were significantly more abundant from dusk to dawn than at mid-day (1200–1600; Fig. 7, ANOVA, Tukey test, $p < 0.05$). Atlantic menhaden and weakfish were significantly more abundant during darkness (2000–0800); abundances observed between midnight and 0400 were higher than at any other time for both menhaden and weakfish (Figs. 4 and 8; ANOVA, Tukey's test, $p < 0.05$).

Fish abundances varied seasonally. Bluefish were significantly more abundant in May and September than from June to August (Fig. 5, ANOVA, Tukey's test, $p < 0.05$). Striped bass and Atlantic menhaden were significantly more abundant in May than at any other time during the year and more abundant in late June than during late July and August (Figs. 4 and 7; ANOVA, Tukey's test, $p < 0.05$). Weakfish were significantly more abundant in late July (Fig. 8, ANOVA, Tukey's test, $p < 0.05$). Atlantic croaker abundance was significantly greater during July and early August while

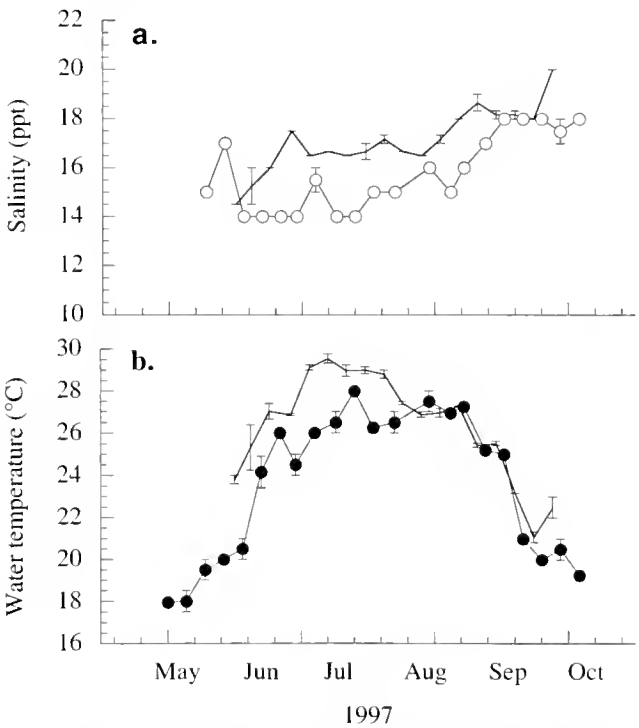

Figure 2. a-Mean salinity (ppt) and b-water temperature (°C) values (±standard error) for Ginney Point and Palace Bar reef, Piankatank River, Virginia from May through September 1997 after Harding and Mann (2001). Data from these two sites were averaged since there was no significant difference in temperature or salinity between sites (ANOVA, $p < 0.05$). Reference mean values for temperature and salinity data from 1993–1996 are plotted with a solid line (± standard error). 1997 data are indicated by lines with symbols (± standard error).

TABLE 1.

Total number of transient fish species collected with gill nets at Palace Bar oyster reef, Ginney Point (oyster bar), and Roane Point (sand bar), Piankatank River, Virginia during 8 thirty-six-hour stations conducted from May 22 to September 3, 1997.

Common Name	Scientific Name	Palace Bar Reef	Ginney Point	Roane Point
Atlantic croaker	*Micropogonias undulatus*	121	120	70
Atlantic menhaden	*Brevoortia tyrannus*	480	455	195
Bluefish	*Pomatomus saltatrix*	65	35	20
Spot	*Leiostomus xanthurus*	221	258	150
Striped bass	*Morone saxatilis*	62	98	10
Weakfish	*Cynoscion regalis*	14	11	7
Blueback herring	*Alosa aestivalis*	3	5	4
Butterfish	*Peprilus triacanthus*	1	0	0
Cownose ray	*Rhinoptera bonasus*	1	0	0
Gizzard shad	*Dorosoma cepedianum*	1	0	0
Hog choker	*Trinectes maculatus*	3	0	0
Silver perch	*Bairdiella chrysoura*	38	3	2
Spotted seatrout	*Cynoscion nebulosus*	4	8	4
Summer flounder	*Paralichthyes dentatus*	0	2	0

spot were significantly less abundant in August (Figs. 3 and 6; ANOVA, Tukey's test, $p < 0.05$).

Fish Assemblage-Habitat Relationships

A detrended correspondence analysis (DCA) using all samples and all species (Fig. 9) aggregated all but one of fourteen species (summer flounder) and all but two of 231 samples (the two samples containing flounder) from all three sites along a single axis virtually on top of each other. This cohesive spatial grouping indicates strong similarity of most species and samples across all sites. Axis I describes a gradient in diurnal light levels moving from left (dark) to right (light). Axis II represents a seasonal gradient in water temperatures moving from bottom (lower water temperatures) to top (warmest water temperatures). The variance explained by the axes was 21.6% (Axis I) and 38.2% (Axis II).

If rare species or species where the total number of fish observed across all three sites was less than fifteen are removed from the analysis, eight species remain (Table 1). A second DCA using only these eight species in the gill net samples (Fig. 10) shows a lack of spatial aggregation of samples by site in ordination space as would be expected by site-specific fish assemblages. Thus, the samples from all three sites show a ubiquitous distribution. Axis I represents a gradient in diurnal light levels moving from left (dark) to right (light). Axis II represents a seasonal gradient in water temperatures moving from bottom (lower water temperatures) to top (warmest water temperatures). Fishes that were more abundant from dusk to dawn during late May, June, and early September (spot, bluefish) are grouped toward the middle of the plot to the left of fishes that were more abundant from dusk to dawn in July (silver perch, weakfish; Fig. 10). Primarily nocturnal species (Atlantic menhaden and spotted seatrout) are grouped to the left (dark) side of Axis I. Striped bass were most abundant in May and early June during daylight hours as indicated by their position in the lower right corner of the plot (Fig. 10). Atlantic croaker were frequently caught between dawn and dusk during the warmer months as indicated by their position in the upper right corner of the plot (Fig. 10). The variance explained by the axes was 28.5% (Axis I) and 48.8% (Axis II).

Species-specific Length Data

Atlantic croaker, Atlantic menhaden, and striped bass observed at Palace Bar reef are significantly larger than fishes of these species observed from either the oyster bar or the sand bar (Table 3; ANOVA, Tukey's test, $p < 0.05$). Spot from the oyster bar are larger than spot from any other site (Table 3; ANOVA, Tukey's test, $p < 0.05$). Bluefish from the reef are slightly but not significantly larger than fish from other sites and weakfish from all sites are of similar length (Table 3; ANOVA, Tukey's test, $p > 0.05$).

DISCUSSION

There was no clear delineation of habitat use by transient fishes along a gradient of estuarine habitat types (oyster reef to sand bar). Atlantic croaker, Atlantic menhaden, bluefish, silver perch, spot, spotted seatrout, striped bass, and weakfish were found in all habitat types examined. The ubiquitous distribution of these common species indicates a lack of site-specific fish assemblages in these habitats. It is unreasonable to expect site-specific groupings of

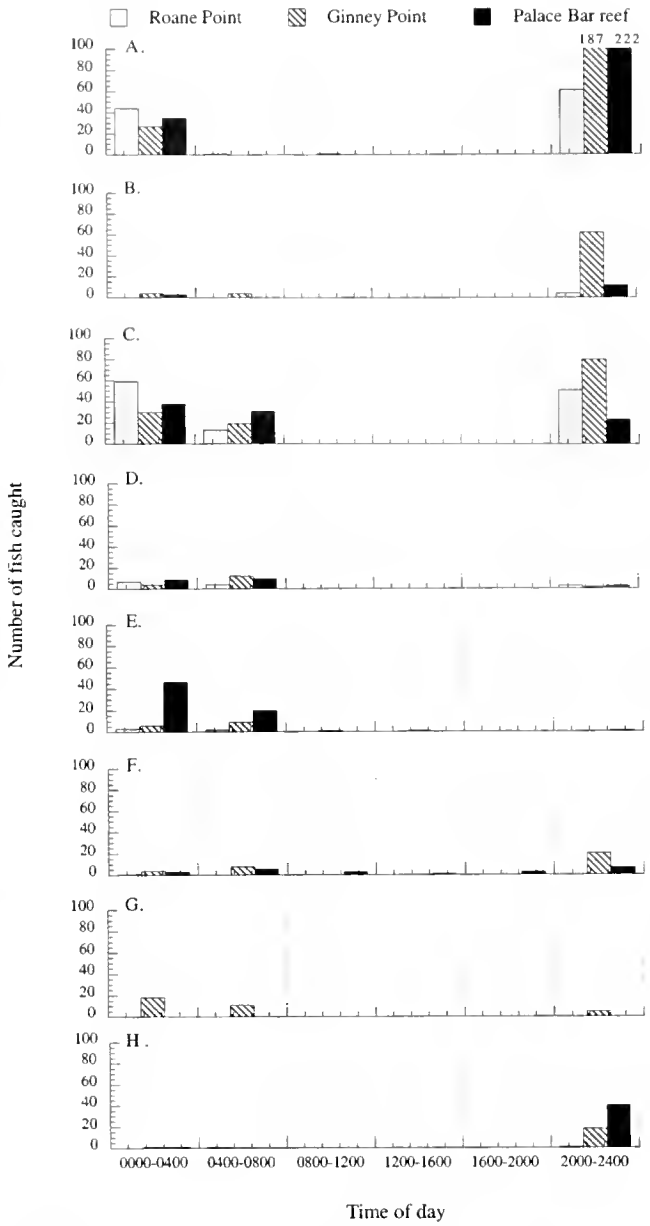

Figure 4. Species-specific abundance for Atlantic menhaden in relation to time of day and day of the year for A.) May 22–23, B.) June 5–6, C.) June 19–20, D.) July 2–3, E.) July 17–18, F.) August 4–5, G.) August 18–19, and H.) September 2–3, 1997.

generalist species such as these that are opportunistically using available habitat. It is more likely that habitat use by these eight fish species relates to variations in habitat quality indicated by habitat-specific productivity.

In general, the smallest fish are found on the sand bar, the site with the least habitat heterogeneity. As habitat complexity increases along the gradient from oyster shell bar through oyster reef, transient fish size and abundance increases. The oyster reef may have relatively higher food availability, a wider diversity of food types because of increased habitat heterogeneity, or greater abundance of high quality food relative to other habitat types. Dietary analyses on bluefish (Harding & Mann 2000) and striped bass (Harding & Mann, unpublished data) from these sites corroborate these functional relationships between reef habitats and transient fishes. Bluefish from sites with oyster shell substrate consume more teleosts than bluefish from the sand bar (Harding & Mann 2001). Bluefish from Palace Bar reef consume a wider diversity of prey items than fish from other sites (Harding & Mann 2001) while reef striped bass consumed more teleosts in general and naked gobies in particular than fish from other sites (Harding & Mann, unpublished data). In other words, the observed differences in fish abundance and size across habitat types may relate to habitat productivity as enhanced by ecological and structural complexity.

Presence/absence and abundance data from this study demonstrate that these transient finfish employ generalist lifestyle strategies (Sale 1980) and are opportunistically using the range of available habitat on a local scale. The habitats of interest herein

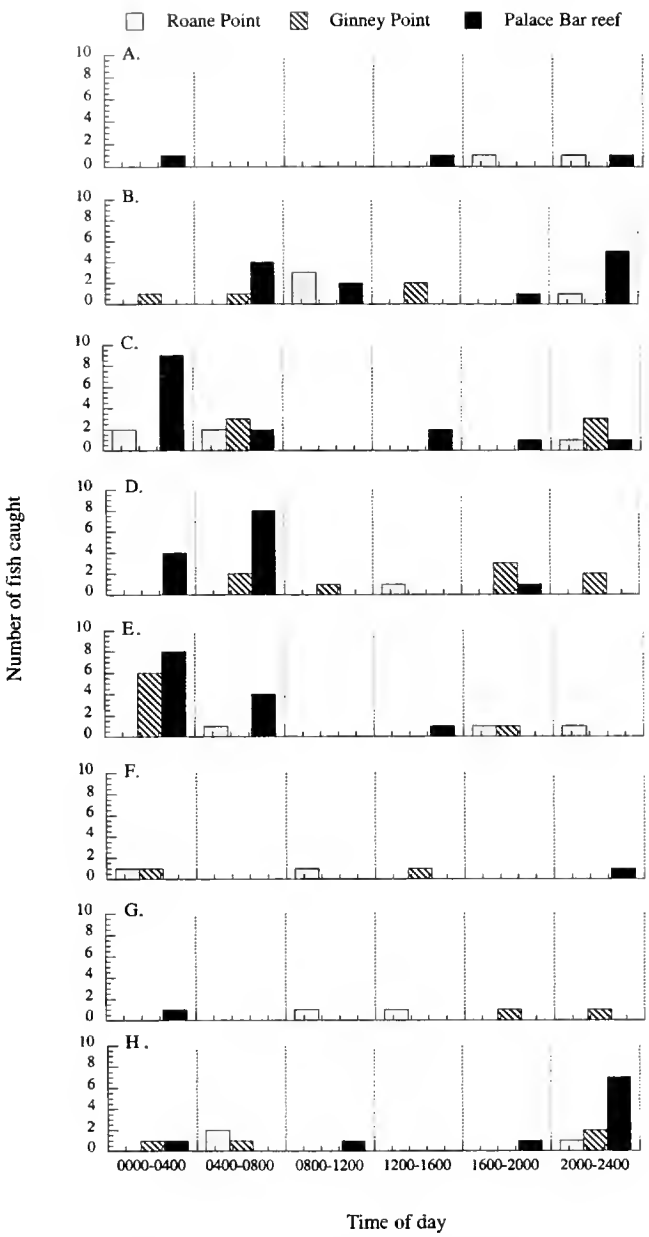

Figure 5. Species-specific abundance for bluefish in relation to time of day and day of the year for A.) May 22–23, B.) June 5–6, C.) June 19–20, D.) July 2–3, E.) July 17–18, F.) August 4–5, G.) August 18–19, and H.) September 2–3, 1997.

represent a gradient or cline of habitat complexity commonly observed in temperate estuaries; namely a cline moving from simple, unstructured hard sand bottom habitats through hard bottom shell habitats with little vertical relief culminating in complex, three-dimensional reef structures created and maintained by oysters. These biogenic reef structures naturally ranged in size from acres to hectares and historically were dominant habitat types in Chesapeake Bay.

This gradient of habitat types is a temperate analog to tropical coral reef systems ranging in scale from patch reefs through much larger reef systems (e.g., the Great Barrier Reef). The transient fish communities associated with temperate and tropical reef habitats are composed primarily of generalists that will opportunistically use available habitat (Sale 1980, Ebling & Hixon 1993, Roberts 1993). The structural and ecological complexity of reef habitats makes them attractive foraging habitat for transient finfish as well as aggregation sites. Historically, shallow portions of Chesapeake Bay were characterized by a mosaic of habitat types including biogenic structure ranging from seagrass beds to oyster reefs extending across spatial scales ranging from kilometers to 10s of kilometers. The development of large biogenic reef structures was facilitated by the evolution of the Chesapeake Bay estuary (Hargis 1999). The parallel development of the Bay's fish fauna favored transient fishes with broad habitat and dietary requirements (generalists) that were able to opportunistically use the dynamic estuarine habitat. These fishes successfully use the modern Chesapeake habitat in spite of relatively recent habitat alterations, namely the decline of both seagrass beds and oyster reefs during the late 20th century.

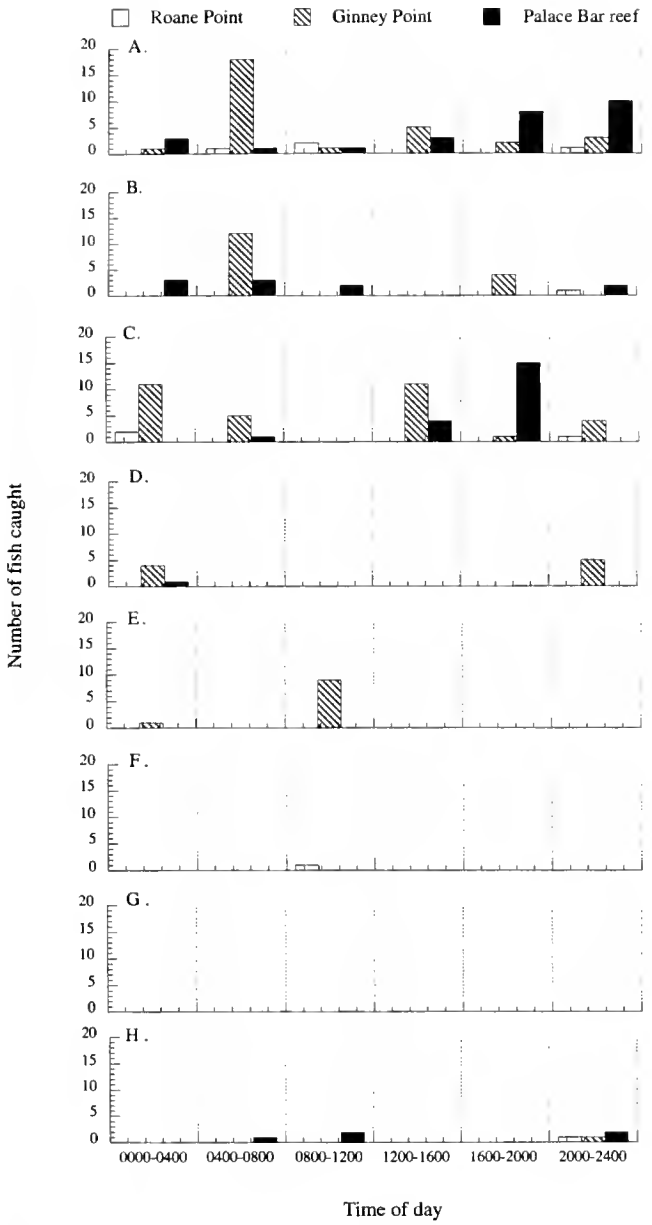

Figure 7. Species-specific abundance for striped bass in relation to time of day and day of the year for A.) May 22–23, B.) June 5–6, C.) June 19–20, D.) July 2–3, E.) July 17–18, F.) August 4–5, G.) August 18–19, and H.) September 2–3, 1997.

Previous discussions of oyster reef habitats as essential fish habitat for transient finfish (Breitburg & Miller 1998, Coen et al. 1999) have examined fish species richness data from a geographic range of oyster reef habitats including both natural and restored reefs of varying ages. Coen et al. (1999) suggest that the use of oyster reef habitats by transient fish species "portends the reef habitats' importance as essential fish habitat, but many functional relationships remain to be evaluated". This study presents a unique comparison of transient fish use of oyster reefs in relation to other locally available habitat types and is the first to provide data to describe fish habitat use at Level 1 (presence/absence), Level 2 (abundance) and Level 3 (size) levels of EFH designation. These data clearly show that these transient generalist fishes do not rely exclusively on oyster reef habitats. From a local historical perspective, the continued presence of these species in the lower Chesapeake in the absence of natural oyster reefs for the past 20+ years (Hargis 1999) is an obvious indicator that oyster reef habitat is not essential for these opportunistic fishes.

The habitat value of oyster reefs to transient fishes is much more complicated than a binary distinction (essential or not essential). Evaluations of oyster reefs as fish habitat must consider reefs in the context of locally available habitat types (per Minello 1999; this study) if accurate descriptions of habitat importance are to be made, particularly for transient finfish species. Continued examination of the functional ecological relationships between oyster reefs and the trophic communities that they support will provide data on which to base habitat distinctions at all four levels of EFH description and related resource management decisions. Gradients

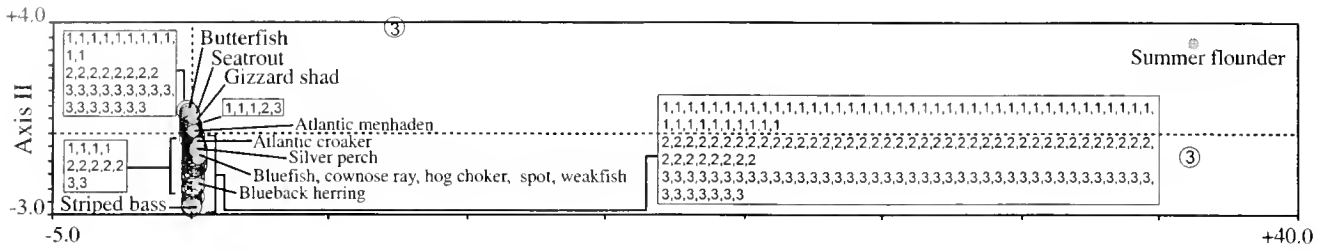

Figure 9. Species-sample biplot for detrended correspondence analyses (DCA) describing transient finfish assemblages and species abundances across a gradient of habitat types ranging from sand bar through three dimensional oyster reef. Fourteen species from two hundred and thirty-one samples collected at Palace Bar reef (1), Roane Point (2), and Ginney Point (3) with gill nets are presented. Axis I represents a gradient in diurnal light levels moving from left (dark) to right (light). Axis II represents a seasonal gradient in water temperatures moving from bottom (lower water temperatures) to top (warmest water temperatures).

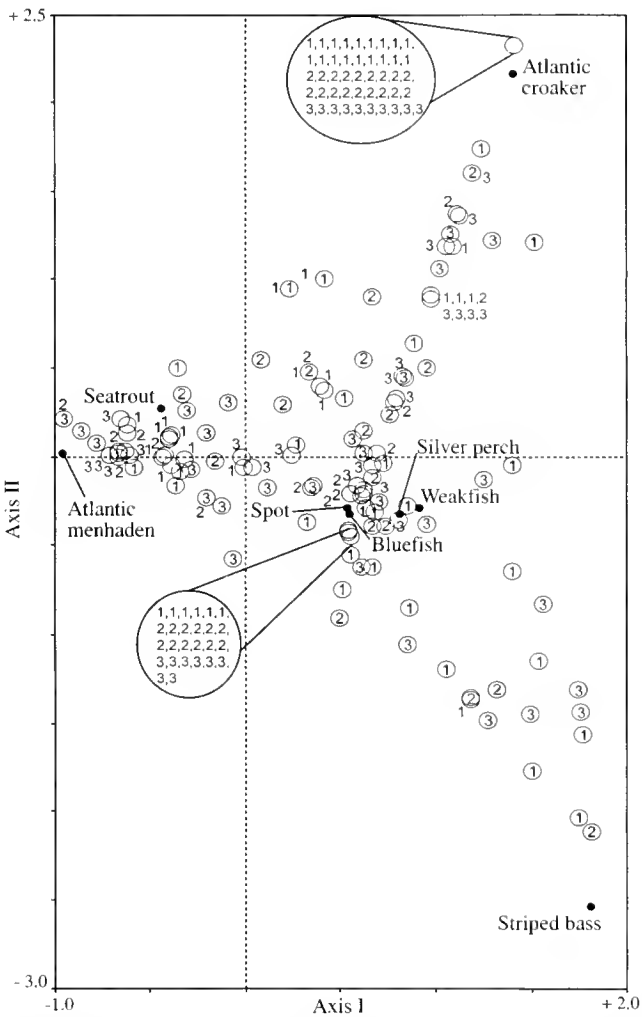

Figure 10. Species-sample biplot for detrended correspondence analyses (DCA) of common fish species across a gradient of habitat types ranging from sand bar through three dimensional oyster reef. Eight species from 201 samples collected at Palace Bar reef (1), Roane Point (2), and Ginney Point (3) with gill nets are presented. Axis I represents a gradient in diurnal light levels moving from left (dark) to right (light). Axis II represents a seasonal gradient in water temperatures moving from bottom (lower water temperatures) to top (warmest water temperatures).

TABLE 3.

Average total length (mm) of the most common transient fish species (standard error) collected with gill nets at Palace Bar oyster reef, Ginney Point, and Roane Point, Piankatank River, Virginia. Site-specific species total lengths were compared with species-specific ANOVAs. Horizontal lines under site-specific species average lengths values indicate sites where statistically similar sizes of a particular species were observed (ANOVA, Fisher's test; $p < 0.05$).

Fish	Palace Bar Reef	Ginney Point	Roane Point
Atlantic croaker	311.6 (3.3)	295.1 (2.8)	290.2 (3.9)
Atlantic menhaden	262.1 (1.9)	246.8 (1.6)	239.7 (1.0)
Bluefish	307.1 (5.7)	298.3 (5.8)	297.1 (6.1)
Spot	199.1 (1.6)	205.1 (1.4)	198.5 (1.7)
Striped bass	294.5 (5.1)	261.7 (3.3)	278.6 (10.7)
Weakfish	286.4 (8.9)	312.4 (20.8)	302 (20.7)

in physical habitat complexity relate to gradients in habitat productivity and thus habitat value or importance. A gradient of terms to describe habitat value that reflects the ecological value of a habitat would be a more realistic tool for habitat distinction. Given their physical and trophic complexity, oyster reefs are important habitat for transient estuarine finfish, however, on the basis of these data, we question the use of term "essential" with regard to oyster reef habitats given the generalist nature of the transient fish species that use these habitats. We suggest that oyster reef habitats are not essential for these fishes but that oyster reef habitats are of higher quality than other locally available estuarine habitat types and thus are better or perhaps even optimal for these fish in terms of growth, reproductive success, and survival.

ACKNOWLEDGMENTS

Support for this project was provided by the U.S. Environmental Protection Agency Chesapeake Bay Program (CB993267-02-1, CB993267-03, and CB993777-01) and the Virginia Institute of Marine Science Department of Fisheries Science. The following

individuals graciously donated their time to assist with field sampling: F. Arazyus, I. Bartol, R. Boger, S. Brooke, J. Brust, N. Clark, V. Clark, C. Conrath, S. Drake, J. Duggan, K. Farnsworth, C. Fennessy, J. Goins, S. Goodbred, A. Hayes, E. Hinchey, K. Hovel, D. Kerstetter, T. Lewis, K. Murray, J. Nestlerode, S. Neubauer, J. Newton, J. Oliver, C. Robertson, V. Roggero, W. Rose, H. Simpkins, M. Southworth, C. Squyars, M. Thompson, B. Trainum, M Wagner, K. Walker, J. Walter, G. White, and H Yarnall. J. Duggan provided valuable assistance designing and building the gill net reel used to store and deploy nets. This is Contribution No. 2429 from the Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA.

IMPACT OF REPEATED DREDGING ON A DELAWARE BAY OYSTER REEF

ERIC N. POWELL, KATHRYN A. ASHTON-ALCOX, SARAH E. BANTA, AND ALLISON J. BONNER

Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Avenue, Port Norris, New Jersey 08349

ABSTRACT The impact of commercial dredging on an oyster reef was evaluated at four sites chosen on New Beds, one of the most important commercial oyster beds in Delaware Bay. Dredging occurred on two of these sites in late October 1999, early and late November 1999, April 2000, and July 2000. Dredging was conducted according to standard industry procedures. Each day, dredging was continuous during approximately an 8-h period. Both one-dredge and two-dredge boats were used. Market-size oysters were culled and sacked in the standard manner. Total dredge coverage for the study was about 240,000 m^2 on each experimental site. The most heavily dredged areas were completely covered by the dredge 4 to 6 times during the study. Two 8-h dredging events within a 10-day period produced barely detectable changes in the oyster population. Minor chipping and abrasion of the shell increased in frequency, but no other discernible impacts were found. Over the 10-mo study that included five dredging events, many of the taphonomic indicators of dredge damage showed time-dependent trends that differed between control and experimental sites. However, these effects were limited mostly to minor chipping and indications of abrasive wear, rather than the more serious aspects of shell damage defined as major chipping, breakage, cracking, and shell perforation. A variety of population health indicators were assayed during the study, including the ratio of live oysters to boxes, condition index, *Perkinsus marinus* infection intensity, and oyster size-frequency distribution. These indicators should have monitored growth, disease pressure, and mortality. Essentially no significant effects could be discerned for any of these measures. Over a very long time, dredging may significantly influence oyster bed physiography and community structure. However, once the bed has become a fished bed, this study suggests that moderate dredging that results in a yearly swept area of no more than four times the area of the bed is unlikely to result in significant further impact on the oyster populations living there.

KEY WORDS: oyster, fishery, dredging, fishing impact, population structure, tophonony

INTRODUCTION

Fishing with bottom-tending gear such as dredges and otter trawls may impact the benthic community in a number of ways. Normally, the impacts are negative to some degree (Collie et al. 1997, Jennings & Kaiser 1998, Thrush et al. 1998). For sessile shellfish in which the efficiency of the dredge is low (Andrews 1988, Giguère & Brulotte 1994, Vølstad et al. 2000), the negative impacts may extend to the target species (Hall 1994, Lenihan & Petersen 1998, Robinson & Richardson 1998). Decreases in growth rate, increases in shell damage, and increased mortality are among the possible impacts that might occur to target shellfish species. In rarer cases, positive impacts may occur. For the oyster, for example, dredging may enhance spat settlement by turning over the shell, and the increased efficiency of capture often observed with repeated dredging should reduce the overall impact of the fishery on routinely fished beds.

Development of a direct-market fishery in the last half of the 1990s on what were historically the Delaware Bay seed beds occurred as a response to the development of Dermo disease, caused by the protozoan *Perkinsus marinus* (Powell et al. 1997). The development of Dermo disease reduced survival on downbay leased grounds so that the historical fishery, based on transplant of seed from upbay seed beds downbay to leased grounds, was no longer profitable. The direct-market fishery, essentially a managed wild fishery, has substantially increased the total amount of dredging on the seed beds that originally supplied seed to the downbay leases.

Yearly stock assessments conducted since the direct-market fishery was initiated have documented a more or less steady decline in oyster abundance on the most heavily fished beds (HSRL 2000). The extent to which this decline is due to the impact of repeated dredging rather than the simple removal of oysters for market is unknown. The general question of the impact of dredging on oyster reefs has received considerable attention over the years. Some have concluded that the impact has been substantial (Marshall 1954, Haven & Whitcomb 1983, McCormick-Ray 1998); others have concluded that the impact has been inconsequential or even positive (Powell et al. 1995). These studies evaluated long-term changes in reef geography, for the most part. In no case has a study been conducted to directly assess the damage to the oyster population caused by repeated dredging of a reef as a normal course of fishing.

Unfished oyster reefs are typified by a complex three-dimensional structure of oyster clumps (Powell et al. 1987, Wilson et al. 1988). Fishing, regardless of the gear used, results in a substantial change in reef micro-topography from this pristine state. However, once the lower-microrelief structure of a commercial reef has been established, the question becomes to what extent will increased levels of exploitation impair oyster population productivity and health? In this study, we have directly evaluated the impact of commercial dredging on oyster population productivity and health on an oyster reef that has, over the years, been one of the most significant commercial producers of oysters in Delaware Bay.

METHODS

Field Program

Two pairs of sites were chosen on New Beds, one of the larger seed beds in Delaware Bay (Fig. 1). Both pairs were located in areas where long-term records consistently showed above-average oyster production. Each site was a rectangle of about 0.2 min longitude by 0.2 min latitude. The two site pairs were separated by 0.2 min latitude. The two sites in each pair abutted each other on one of the four sides (Fig. 1). The two sites in a pair were randomly designated as either an experimental site or a control site. These sites were, for the controls, C1 (grid 2) and C2 (grid 37), and for

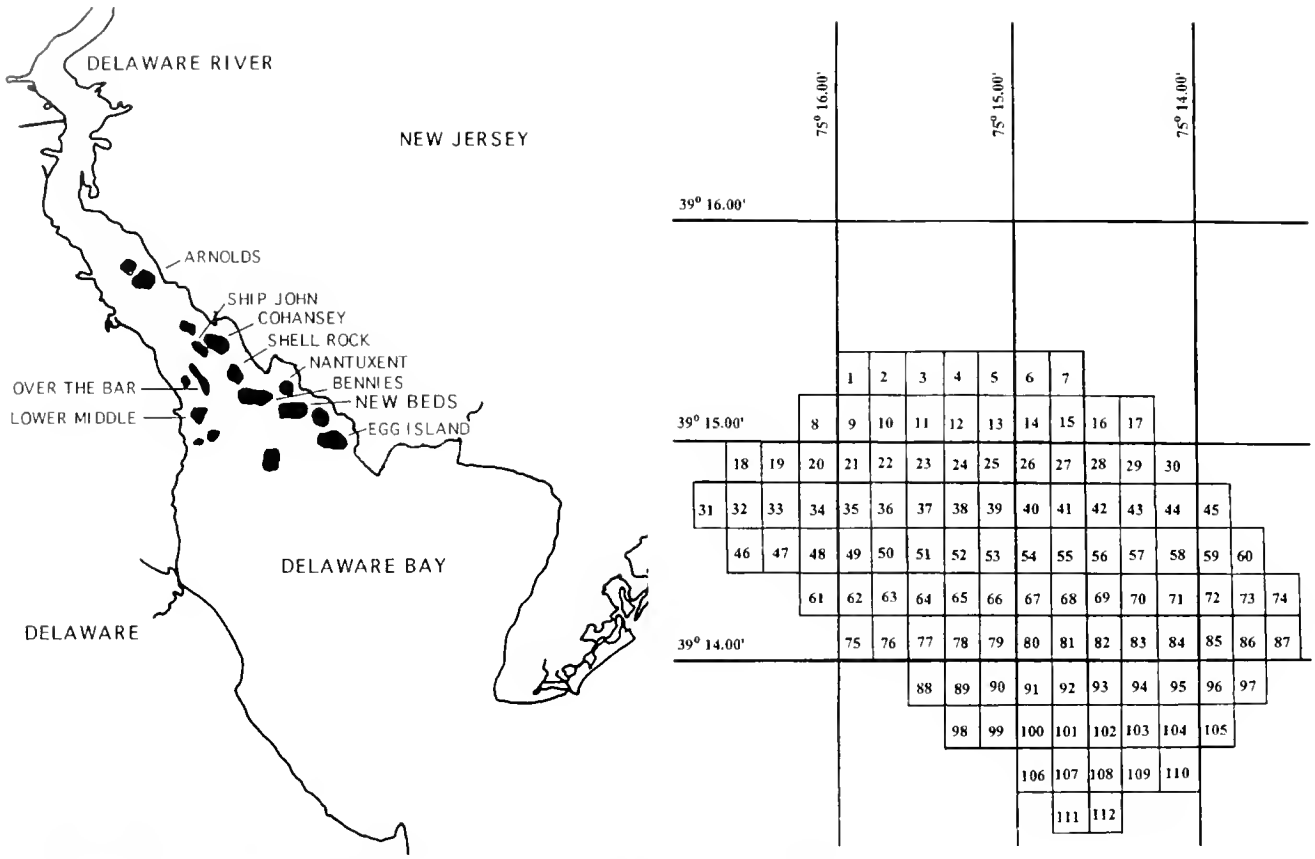

Figure 1. Map of Delaware Bay showing the location of New Beds where the study was conducted and the position of the four sites, grids 2, 10, 36, and 37, on New Beds.

the experimentals, E1 (grid 10) and E2 (grid 36) (Fig. 1). (Fegley et al. [1994] describe the bed gridding system used in Delaware Bay.) Dredging was conducted on the experimental sites.

The four sites were sampled in late October 1999, prior to initiation of dredging. Subsequently, dredging occurred on each experimental site in late October 1999, early and late November 1999, April 2000, and July 2000. Samples were taken from each site prior to dredging, except in November when samples were taken after dredging. The sites were sampled one last time in August 2000.

Between dredging events, fishing should not have occurred on any of the sites. Each site was designated as closed to fishing by the New Jersey Department of Environmental Protection (NJDEP). All of New Beds was closed from Fall 1999 into Spring 2000, thus limiting any chance of fishing unknown to us during most of the experiment. New Beds reopened in May 2000 so that some dredging unknown to us might have occurred on the sites during Summer 2000; however, the sites were buoyed and the NJDEP checked the sites routinely so that any impact of the fishery during that time was certainly minimal in comparison to our efforts.

Dredging was conducted according to standard industry procedures. In the Delaware Bay fishery, some boats carry two dredges, operated port and starboard, and some boats carry one dredge, typically deployed aft. The standard dredge used by nearly all boats has a mouth opening of 1.27 m. Accordingly, we used both a one-dredge and a two-dredge boat, alternating between the two from one dredging event to another, and we used a 1.27-m dredge. Each day, the boat arrived on site around 7:30 AM and ceased fishing around 3:30 PM. Dredging was continuous during the 8-h period. Market-size oysters were culled and bushels were sacked in the standard manner. A New Jersey bushel is about 37 L.

Three one-bushel samples were taken for analysis on the last three dredge hauls of the day in 1999 and prior to dredging in 2000 on the experimental sites and on three randomly selected locations on the control sites each time the experimental site in the pair was sampled. As the tows in the experimental site were taken during the normal course of fishing, they were taken quasi-randomly in that portion of the experimental area receiving the heaviest dredging impact. To maintain consistency, tows in the control area were taken in the same manner (time, distance, etc.). During dredging and sampling, a data logger recorded DGPS position and time at 5-sec intervals. The log was annotated each time a dredge was released or retrieved and each time a sack of oysters was filled.

Laboratory Bushel Sample Analysis

Each bushel sample was sorted into live oysters, boxes (dead, articulated valves), shell, and debris, and the respective volumes were measured. The assumption was that boxes represented recent mortality (Christmas et al. 1997). During sorting, the presence of selected fouling organisms was recorded as absent, present, or abundant. These included the red-beard sponge *Microciona*, the boring sponge *Cliona*, the sabellariid polychaete *Sabellaria*, and serpulid polychaetes. Oyster drills, *Urosalpinx* and *Eupleura*, were counted. The presence of drill egg masses and the flatworm *Stylochus* were recorded. Mud crabs were evaluated as absent, present

Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

or abundant. The longest dimension of each oyster and box >20 mm was measured. The number of live and dead spat <20 mm was counted. Wet meat weights were taken for each live oyster. At the same time, a random sample of 10 oysters per bushel was selected for *P. marinus* analysis. Mantle and rectal tissue were taken for analysis of infection intensity following standard procedures (Powell & Ellis 1998).

A taphonomic assessment was made for each box and live oyster. The following types of damage were recorded as present or absent on each individual: minor chipping on the shell margin, major chipping on the shell margin, presence of perforations through which tissue could be observed or, for boxes, through which the inside of the shell could be observed, cracking without breakage, and presence of abrasions. Minor and major chipping were distinguished by assigning to the major category cases where small chips were distributed around most of the shell margin or cases where larger pieces of shell were missing. Abrasions were apparent dredge drag marks or cases where the surface of the shell had broken off. Typically, the latter occured on shell heavily bored by clionid sponges. For more information on approaches to taphonomic analysis, we refer the reader to Davies et al. (1990).

Swept Area and Catch per Unit Effort (CPUE) Analysis

Swept area was calculated for each dredge tow from the 5-sec position logs and the dredge width. Site coverage was estimated by dividing the site into 10 × 10-m squares, 100 m^2 in area, and calculating the total swept area in each of these squares. The choice of a 10 × 10-m square was made primarily for ease of data analysis and presentation; however, the dimensions were considered to be the smallest areal dimension that was distinctly larger than the accuracy for which dredge position was known. Dredge position was judged to be accurate within 5 to 10 m. Accuracy was

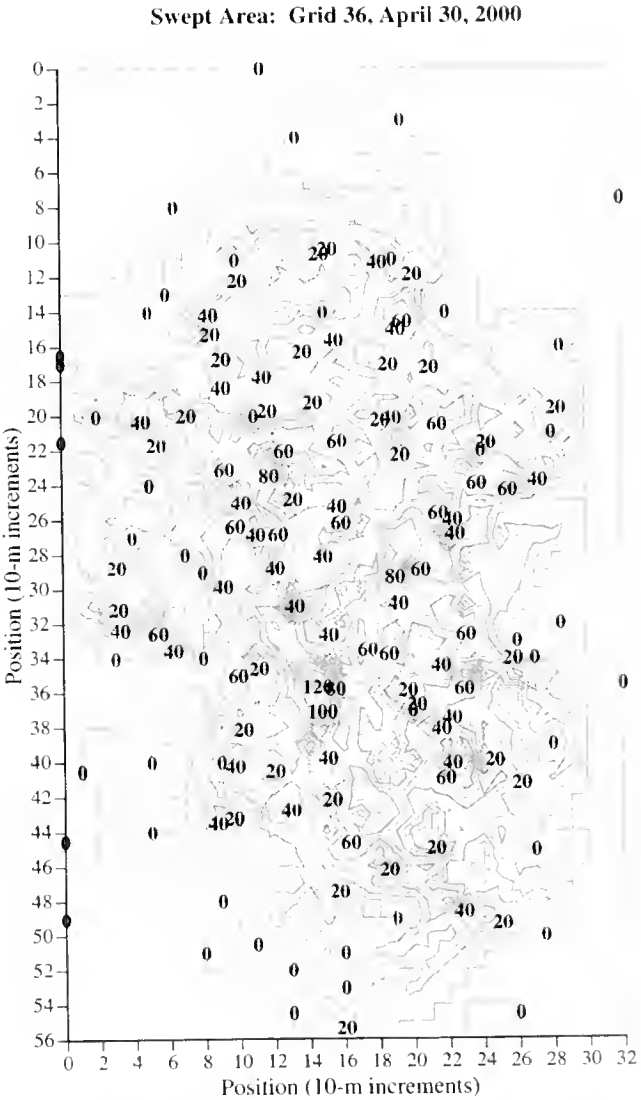

Figure 3. Coverage map of grid 36 (one of the two experimental sites) for an 8-h dredging event that occurred on April 30, 2000. Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

greater for the two-dredge boat because the dredge was released port and starboard forward of amidships, whereas the single-dredge boat released the dredge from the stern. Coverage was assumed to be 100% if the total swept area in a 10 × 10-m square during a single daily event reached 100 m^2.

Samples for analysis were obtained from typical dredge tows. A typical dredge tow covered about 300 to 600 m^2 and intersected 40 to 45 10 × 10-m squares. Individual 10 × 10-m squares were not sampled for this report.

CPUE was calculated as the number of bushel sacks per square meter of dredged area. The number of market-size oysters per sack averaged 318.

Statistical Analysis

Most statistical analyses used ANOVA with all interaction terms. Block (the site pairs), treatment (experimentals and controls), and in some cases, time were class variables. For time trends in CPUE, a Spearman's rank correlation was used. For ANOVA analyses, data on number and volume were normalized to the total volume of shell per bushel (the sum of the volumes of live oysters, boxes, and shell). This was done because the bushel sample did not come from a known area—the dredge catches much more than one bushel—and the volume of debris including biont overgrowth was not a constant over the study, whereas to a first approximation, the volume of shell was. To further assess the influence of using differing sample sizes, we also conducted analyses on ratios of variables, such as the ratio of live oysters to boxes. Such ratios are not influenced by the volume of sample collected. With the exception of presence-absence data that were recorded as a 0 (absent) or a 1 (present), all variables were ranked prior to analyses. Consequently, all statistical analyses were effectively nonparametric. Finally, analyses using variables that potentially were influenced by size, such as Dermo infection intensity, condition index, etc., included size class as a class-variable covariate (Underwood 1997). Size classes were juvenile (20–63.4 mm), submarket (63.5–76.2 mm), and market (>76.2 mm).

RESULTS

Swept Area Coverage

The one-dredge boat addressed an average of 37,039 m^2 of bottom during a single 8-h day. The two-dredge boat addressed

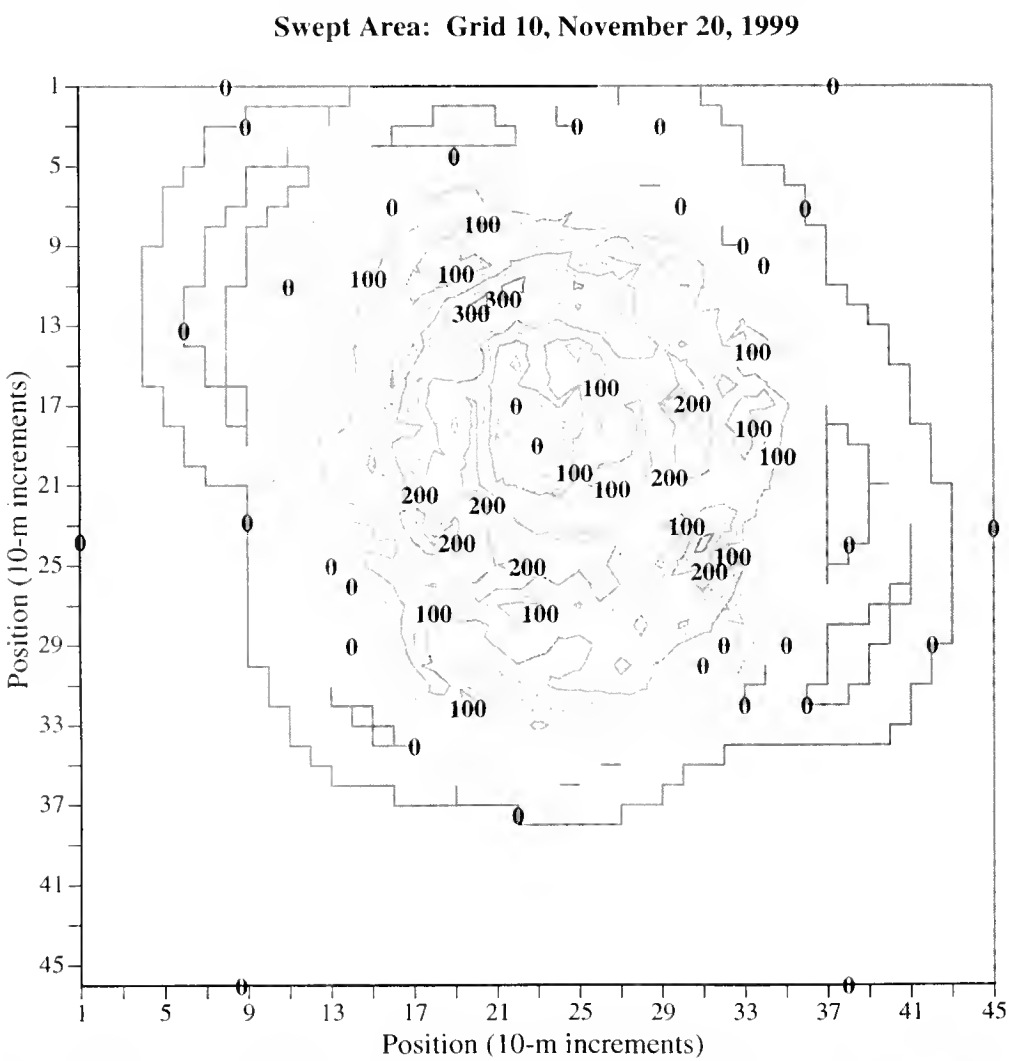

Figure 4. Coverage map of grid 10 (one of the two experimental sites) for an 8-h dredging event that occurred on November 20, 1999. Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

nearly twice that area, 63,606 m^2 on average, because both dredges were on the bottom for much of the day. The pattern of dredging tended to be circular to elliptical around a central point within the 0.2 min latitude by 0.2 min longitude site. Thus, a differential impact occurred over the experimental site, with greatest impact near the epicenter and with the impact steadily decreasing to near-zero at the edge of the site. Daily coverage typically ranged from 50 to >100 m^2 per 10 × 10-m square, meaning that 50% to >100% of a 10 × 10-m square near the epicenter was covered by the dredge during that day. Examples of individual trips are shown in Figures 2 through 5. Total coverage for the study is depicted in Figures 6 and 7. In the heavily dredged central areas of each experimental site, coverage in a 10 × 10-m square varied from 300 to >600 m^2 by the end of the study. That is, an area equivalent to the entire area of a 10 × 10-m square was impacted in that 10 × 10-m square by the dredge three to six times during the study. Although we cannot unequivocally show that each square meter in the 10 × 10-m square was addressed by the dredge three to six times because the position of the dredge on the bottom is not known precisely, certainly we can assume that the entire 10 × 10-m area of such a square was impacted multiple times.

Daily and Cumulative CPUE

CPUE was calculated each time a bushel sack was filled during the day to determine whether the rate of capture declined (Fig. 8). CPUE did not change significantly over the course of the day for any of the 10 dredging events (five 8-h events, two experimental sites; Spearman's rank correlation, $\alpha = 0.05$).

Site Status at Study Inception

All four sites, the two experimental sites and the two control sites, were sampled prior to the initiation of dredging. ANOVA analyses revealed that the experimental sites diverged from the control sites significantly for a few variables, including the amount of fouling ($P = 0.02$), taphonomic status (boxes only, $P = 0.0001$), and condition index ($P = 0.0001$). The significant difference in taphonomic status came from significant differences in

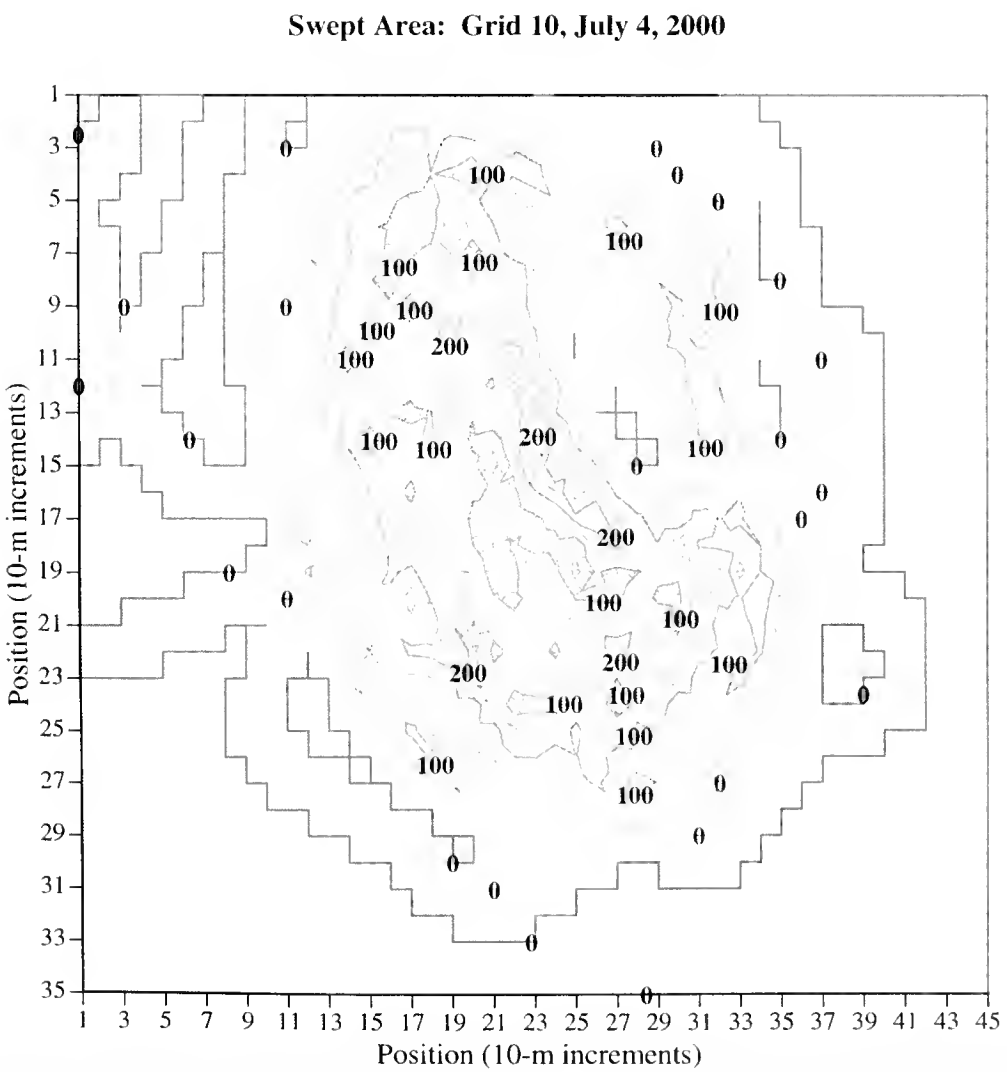

Figure 5. Coverage map of grid 10 (one of the two experimental sites) for an 8-h dredging event that occurred on July 4, 2000. Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

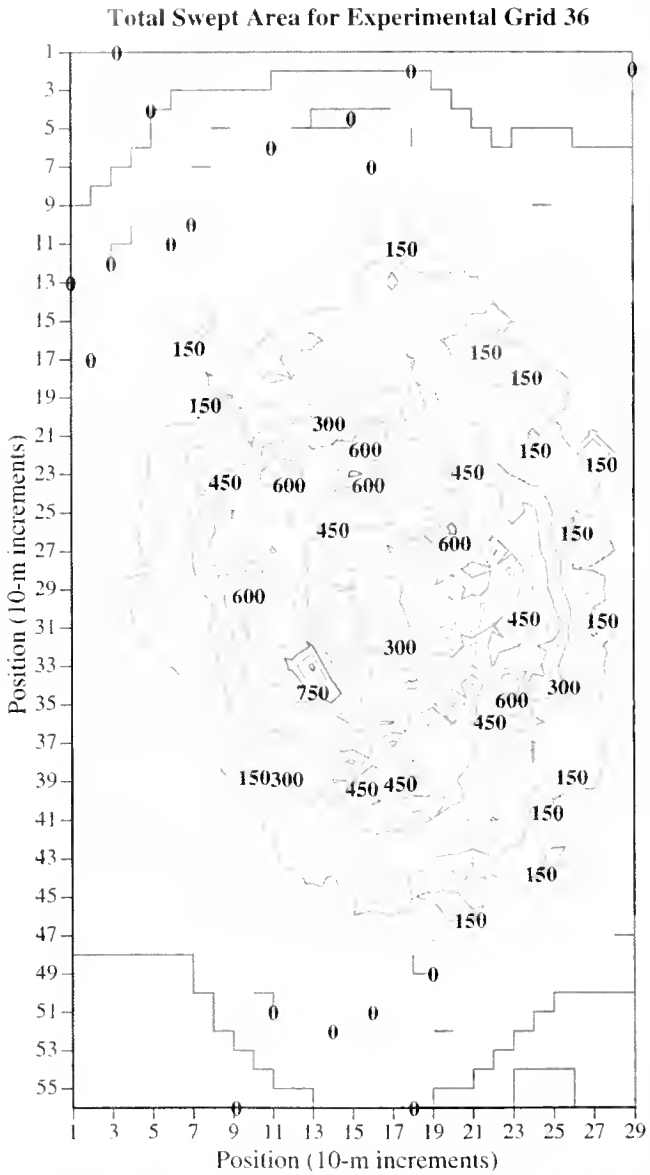

Figure 6. Cumulative coverage map of grid 36 (one of the two experimental sites) for the entire study (five 8-h dredging events = 40 h of dredging). Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

minor chipping and abrasion. Because of the imperfect nature of the controls (e.g., Lindegarth et al. 2000), the evaluation of the effects of dredging will focus on the significance of interaction terms between treatment and time in further analyses.

Immediate Impact of a Dredging Event

The question of the immediate impact of dredging was assessed at the time of the first two dredging events, which took place within 10 days of each other in late October/early November 1999. In this case, the experimental sites were sampled before the first event and after the second.

In only one case was a uniform effect on the two experimental sites found. Minor chipping of live oysters increased after dredging on both experimental sites (Table 1). In general, the incidence of dredge damage increased in live oysters and boxes after dredging (Table 1). In general, the increase in dredge damage was similar for boxes and live oysters. However, 16 h of dredging did not result in significant changes in oyster health as measured by mortality, *P. marinus* infection intensity, or condition index. Such a result might be expected, however, because the samples were taken immediately after the second 8 h of dredging had been completed.

Influence of Coverage

Coverage, defined as the total swept area for the dredge, increased at each experimental site with each dredging event in the time series (Fig. 9). This increase was not uniform over the experimental site, however. Dredging tended to be heavier in some portions of the site than in others (Figs. 2–5). As a result, when a sample was taken, the coverage for the specific area sampled differed, sometimes considerably, between the three replicate samples. This local variation in coverage within an experimental site might differentially influence each of the three samples taken each time period. Because the market-size oysters are sorted from the total dredge haul onboard the boat while the boat is underway, and the remaining material subsequently redistributed in a quasi-random manner over the site, one might not expect significant relationships to exist between the coverage of any specific set of 10 × 10-m squares and the status of the oysters, boxes, and shell located there after dredging had ceased. This is particularly true in our case where any one sampling tow intersected 40 to 45 10 × 10-m squares over the 300 to 600 m distance of the tow. Nevertheless, if such a relationship did exist, coverage of necessity would have to be included in the statistical analysis as a covariate. Accordingly, we examined the degree to which the three samples at a given site and sampling period differed as a function of the coverage recorded for the specific area of the site from which each sample was taken.

Instances where differences in coverage between the three samples significantly impacted a variable within each site and sampling time did not occur more often than expected by chance (binomial test, $\alpha = 0.05$), as anticipated from the dredging and onboard culling process and the length of the sampling tows. Accordingly, coverage was not included as a covariate in further analyses.

Cumulative Impact of Dredging

As time passed and more dredging events occurred on the experimental sites, the difference between the control sites and experimental sites might be expected to diverge. Such variance would be evidence of long-term impacts of dredging. Accordingly, we examined the time series for significant interaction terms between time and treatment. Because we anticipated that the similarity of the control and experimental sites should decrease over time as dredging impact accumulated on the experimental sites, we also examined the level of significance achieved in comparisons of control and experimental sites at each individual time period when a significant "time*treatment" interaction occurred. We expected the difference between control and experimental sites to reach increasingly higher levels of significance as time passed and the cumulative impact of the dredge increased.

Changes in taphonomic status can be expected to occur as

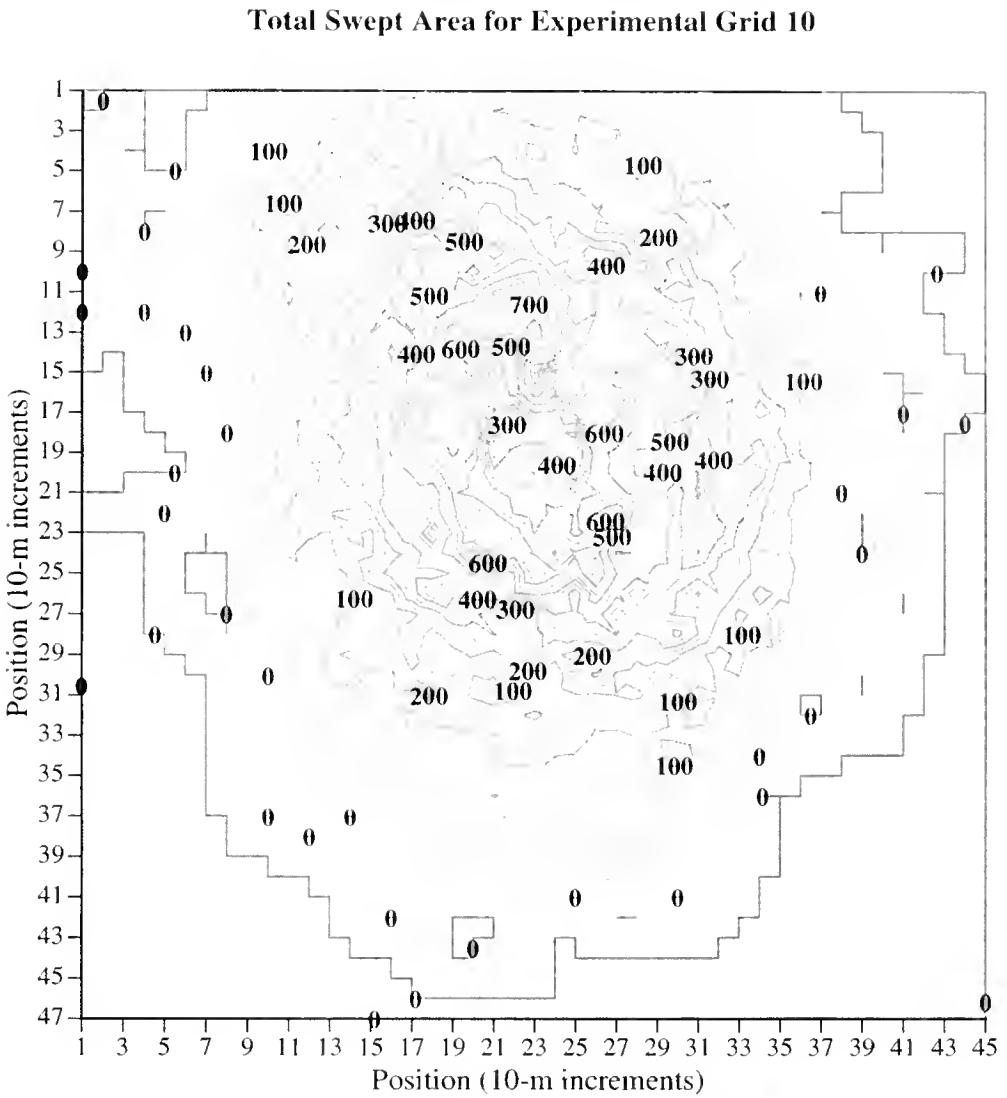

Figure 7. Cumulative coverage map of grid 10 (one of the two experimental sites) for the entire study (five 8-h dredging events = 40 h of dredging). Position is identified on the *x* and *y* axes as the number of 10-m intervals with the (0,0) location in the northwest corner. Contours are the total swept areas dredged in each 10 × 10-m section. Contours were generated from the total estimated coverage for each 10 × 10-m square.

dredging occurs. Indeed, the time*treatment interaction term was significant for total taphonomic impact and for many of the individual taphonomic indicators for live oysters and for boxes (Table 2). However, a consistent pattern over time did not occur. Oysters from experimental sites were more heavily damaged in November and July and less heavily damaged in April, for example (Table 2, Fig. 10). Minor chipping rose slightly over the winter and declined into the summer, presumably as the oysters were able to add new shell, thereby removing the evidence of old chips (Fig. 11). Oysters from the control sites and experimental sites followed very similar patterns in that the incidence of minor chipping declined simultaneously in both. Similarly, abrasive wear rose throughout the study for oysters from both the experimental and control sites (Fig. 12). Oysters from the experimental and control sites differed significantly in the incidence of abrasion in late November, April, and July, but the relationship was inconsistent over time. Abrasion was more common in oysters from control sites than from experimental sites in April and was less common at the other two times. More severe forms of shell damage such as breakage, cracking, and shell perforation occurred rarely (Fig. 13), and were not statistically related to the presence or absence of dredging.

Boxes followed a similar pattern. Boxes from the control sites diverged from the experimentals at the beginning of the experiment, but subsequently did not differ much (Fig. 10). The instance of minor chipping declined in the summer (Fig. 11). The frequency of abrasion rose over the course of the experiment, though less regularly than for live oysters, and boxes from experimental sites diverged from the control boxes only at the inception of the study (Fig. 12). Not surprisingly, considering the similarity of the boxes and live oysters throughout the study, the ratio between the two for the various taphonomic indicators varied little (Table 2, Fig. 14).

Oysters from the control and experimental sites differed little beyond the taphonomic indicators of dredge damage. Time*treatment interaction terms were not significant for the ratio of live oysters to boxes, indicating that the pattern of mortality did not change between control and experimental sites (Fig. 15). The ratio

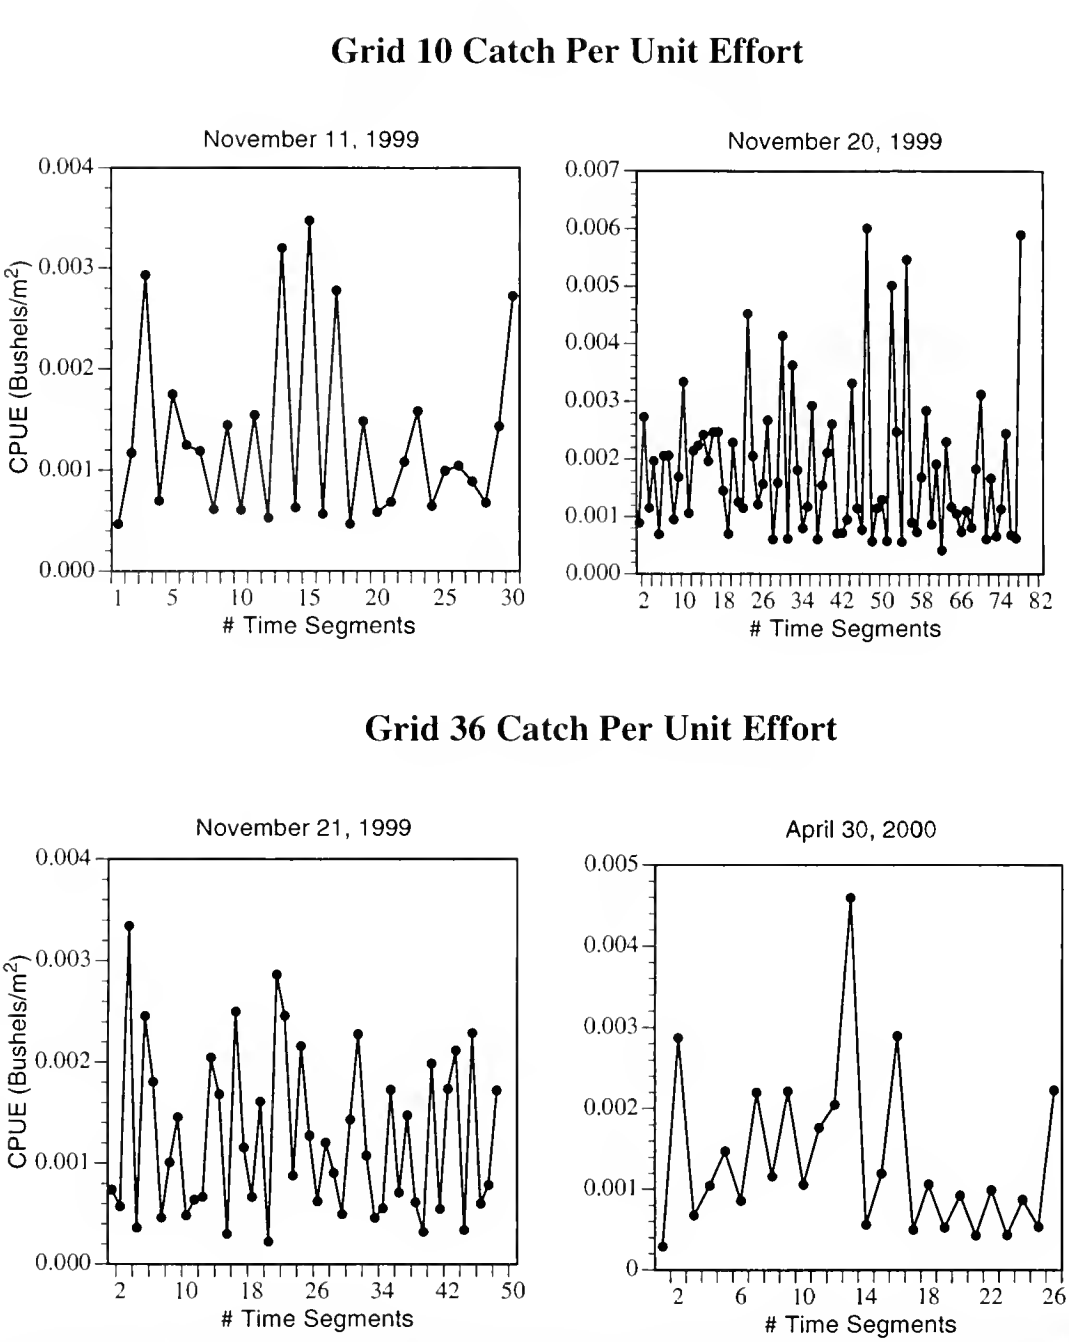

Figure 8. Examples of time trends in CPUE for daily dredging events. CPUE is measured in bushels caught per square meter of swept area. The *x* axis records consecutive time segments when one or more bushel sacks were filled. Each CPUE estimate is based on the swept area during that time segment.

of juveniles to submarkets and submarkets to market-size oysters also did not change, indicating that the processes of growth and mortality changed in similar ways in oysters from control and experimental sites. The time*treatment interaction was significant for condition index, but this result was principally due to the divergence of the experimental and control oysters at the beginning of the study (Table 2). Subsequently, condition index declined slightly over winter in both treatments, rose somewhat into the summer, and then declined again, as is typically the case in Delaware Bay (Fig. 16). Thus, the experimental and control sites yielded very similar values of condition index throughout the study.

DISCUSSION

Coverage and Short-Term Impacts

Total dredge coverage for the study was about 240,000 m^2 on each experimental site (Fig. 9). The most heavily dredged areas were completely covered by the dredge four to six times during the study. This degree of impact is somewhat greater than is typical for the Delaware Bay seed beds under the direct-market harvesting scenario that exists today. Estimates of swept-area coverage in 2000 by industry vessels during the fishing season range from about 50% to 800% of bed area (the latter indicating that the bed

TABLE 1.

Results of ANOVA tests on time for the first two dredging events that took place within 10 days of each other in late October/early November, 1999, in which the condition of the site before and immediately after 16 h of dredging was compared. *P* values under the time and time*site columns record the results of ANOVA analysis for the variable time (before vs. after dredging) and the interaction term with site (the two experimental sites). The column "?Site" records which of the two sites, E1 or E2, were significantly different. The directional arrows indicate whether dredging resulted in an increase (up) or decrease (down) in the variable. Only taphonomic indicators showing significant results are shown. NS, not significant ($\alpha = 0.05$).

was completely dredged eight times in 2000, depending on the seed bed, but only one bed exceeded 150% of bed area (1.5 times; Banta et al. unpubl. data). Average coverage for the fished oyster beds in 2000 was 84%. Thus, our study produced dredge swept-area coverages of approximately double to triple the oyster fishery's impact on an average heavily fished oyster bed in Delaware Bay. It follows that any impacts recorded in this study are likely, on the average, to be more severe than typically observed under normal fishing activities in Delaware Bay.

Sixteen hours of dredging, two 8-h events within a 10-day period at the beginning of the study, produced barely detectable changes in the oyster population. Given the rigorous nature of dredging, one might anticipate that shell cracking and breakage would occur often enough to be readily detected. In fact, these severe forms of impact occurred rarely. The incidence of cracking and breakage did not normally exceed about 2% of the live oysters, and major chipping was restricted to about 20% of the population. These more serious forms of shell damage did not increase in frequency after 16 h of dredging. Minor chipping and abrasion were more common, about 70% of the oyster population had minor chipping and a more variable number, 10% to 50%, showed evidence of abrasion. These latter two less serious forms of dredge damage did increase in frequency after a 16-h period of dredging. However, no other discernible impacts were found.

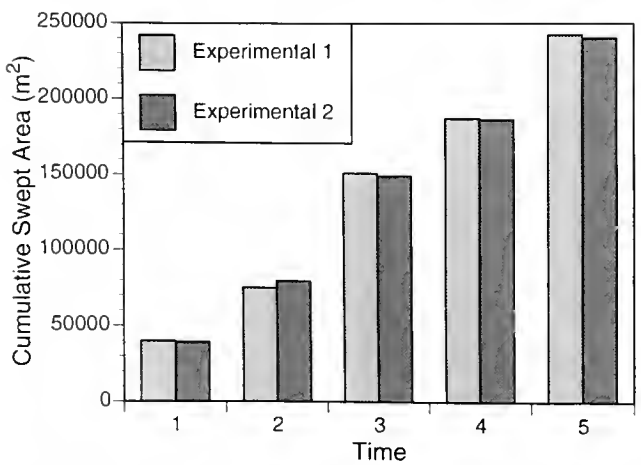

Figure 9. Cumulative swept-area coverage for the two experimental sites. Time segments are defined in Figure 10.

Long-Term Impact: Dredge Damage

Dredge coverage accumulated at an average of about 47,500 m^2 per 8-h event on each experimental site (Fig. 9). Although the impact of a single event was barely measurable, dredge damage might be expected to accumulate over the study. No such trend was observed.

Many of the taphonomic indicators of dredge damage showed time-dependent trends that differed between control and experimental sites. However, for the most part, these effects were limited to minor chipping and indications of abrasive wear, rather than the more serious aspects of shell damage defined as major chipping, breakage, cracking, and shell perforation. Furthermore, the anticipated divergence between control and experimental sites was most noticeable on the sampling dates that immediately preceded and followed the winter months. By summer, most differences had disappeared.

Two possible reasons exist for the failure of dredge damage to accumulate over the study as might have been anticipated. (1) The taphonomic indicators might represent damage that occurs from sources other than dredging. Certainly, chipping and breakage can be predator induced, for example (McDermott 1960, LaBarbera

TABLE 2.

Results of ANOVA tests on time for the full time series of dredging events. *P* values under time*treatment, time*treatment*block, time*treatment*size class, and time*treatment*block*size class record the results of ANOVA analysis for interaction terms with time and treatment. *P* values given under the Time columns (1, and 3–6) represent significant treatment effects obtained from ANOVA analysis for that time only. These times correspond to those given in Figures 10–15. The absence of Time 2 in the table results from the absence of control samples at that time (this was the second sampling of the experimental site taken immediately after the first two dredging events). Only taphonomic indicators showing significant results are shown. NS, not significant ($\alpha = 0.05$). –, not applicable.

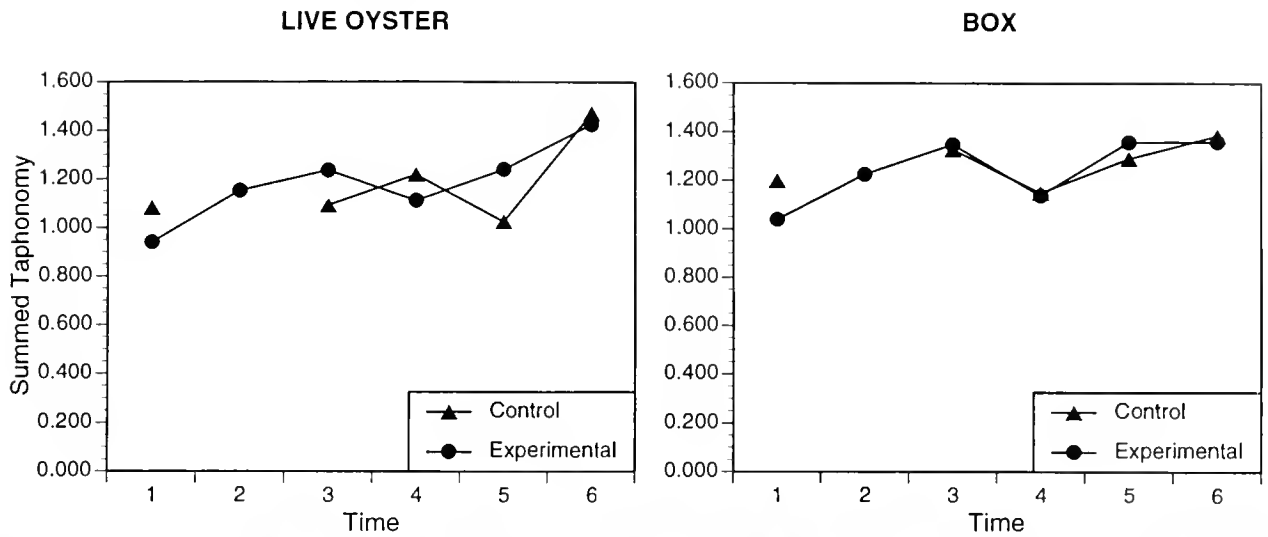

Figure 10. Time-dependent changes in the taphonomic condition of live oysters and boxes during the study. Taphonomic condition is calculated as the sum of minor chipping, major chipping, abrasion, breakage, cracking, and shell perforation. For example, if two of these conditions were present, the sum recorded would take the value of 2. Time segments are: 1, October 30–31, 1999; 2, November 11–13, 1999; 3, November 20–21, 1999; 4, April 28–30, 2000; 5, July 2–4, 2000; 6, August 31, 2000.

1981, Elner & Lavoie 1983). (2) Rapid repair of minor shell damage may mitigate the dredging impact. Repair should occur most rapidly during the warmer months and, in fact, the incidence of minor chipping decreased substantially during the summer. This decrease suggests that rapid shell repair during the warmer months is an important mechanism minimizing the observable impact of dredging, although some effect on the animal's energy budget, in diverting energy to shell growth, might be anticipated (Bernard 1974).

The incidence of abrasive wear increased throughout the study on both sites (Fig. 12). Abrasion on the shell surface cannot be repaired and so would be expected to accumulate. However, the fact that this taphonomic indicator increased in both the experimental and control oysters suggests that its origin is something other than dredge damage. Increased clionid activity was noted during the study (Fig. 17) and would explain this observation.

Juvenile, submarket, and market-size oysters might be expected to differ in their sensitivity to shell damage by dredging. No evidence could be obtained for a differential effect in this study, however.

Long-Term Impact: Population Health

One assumes that oysters, like other bivalves, respond at the physiological level to the stress of capture and release (Pekkarinen & Suoranta 1995). No physiological indices of stress were evaluated in this study. However, a variety of population health indicators were assayed during the study that should integrate changes in underlying physiological state via measures of growth, disease pressure, and mortality. These variables included the ratio of live oysters to boxes, condition index, *P. marinus* infection intensity, and ratios between oyster size classes.

Essentially no significant effects could be discerned for any of these measures. The ratio of live oysters to boxes remained relatively similar between control and experimental sites (Fig. 15). Even when the oyster and box populations were apportioned into three size classes, the ratio of live oysters to boxes was not influ-

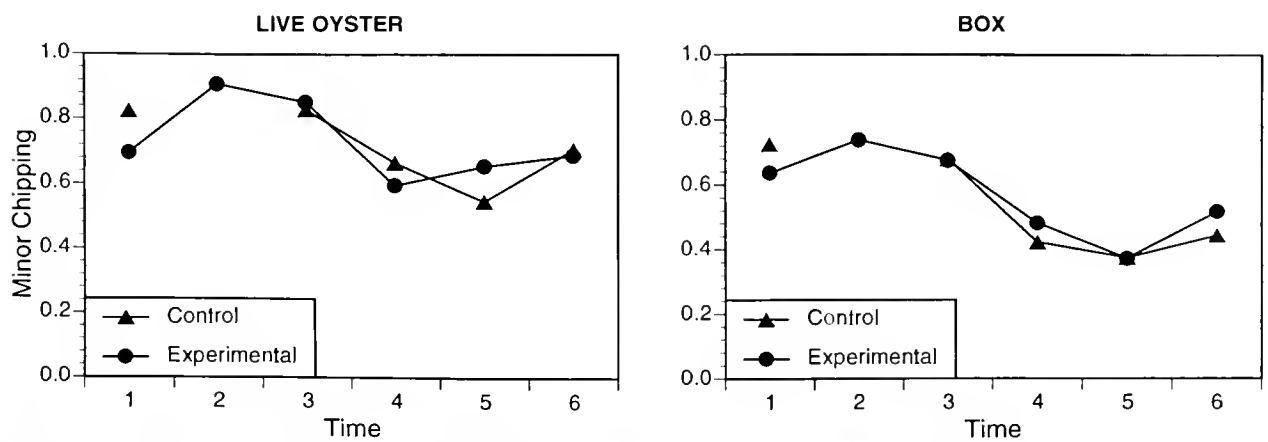

Figure 11. Time-dependent changes in the the frequency of minor chipping of live oysters and boxes during the study. Time segments are defined in Figure 10.

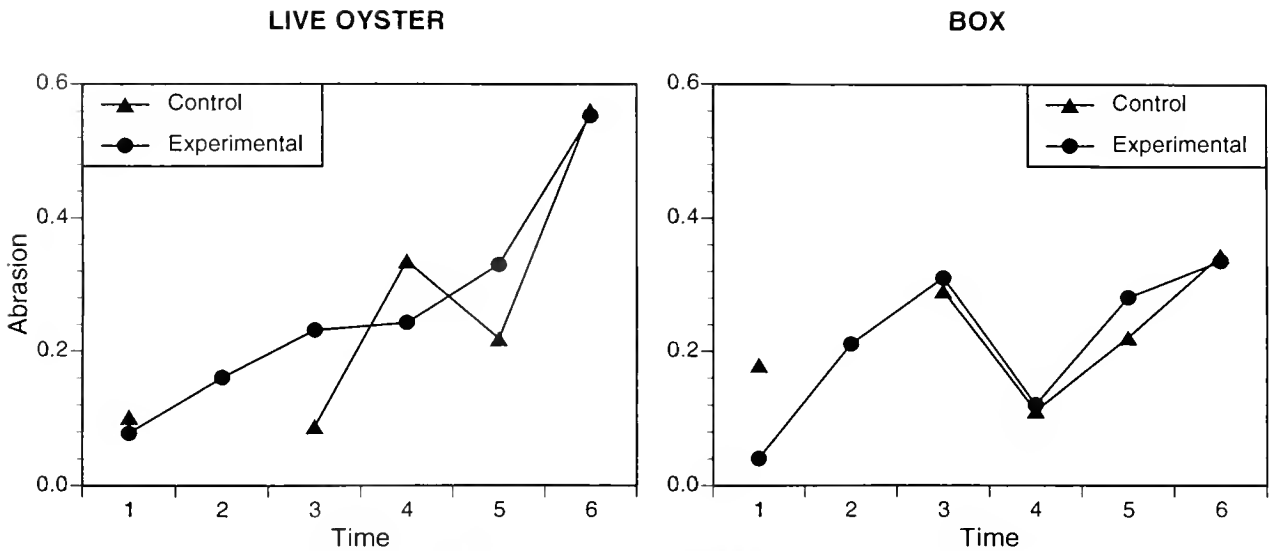

Figure 12. Time-dependent changes in the frequency of abrasion of live oysters and boxes during the study. Time segments are defined in Figure 10.

enced significantly by repeated dredging. Thus, certain size classes were not differentially affected. The ratio of juvenile to submarket oysters and submarket to market-size oysters similarly did not diverge significantly over time between the control and experimental sites. *P. marinus* infection intensity was also unaffected. Dredging, in the degree conducted in this study, did not measurably impair oyster growth, mortality, or population health.

Because the fishing effort resulted in the removal of market-size oysters from the experimental sites, the ratio of submarket to market-size oysters in the experimental and control sites might have been expected to diverge over time. This did not occur because the industry dredge efficiency averaged between 4% and 7% (Banta et al. unpubl. data). Thus, despite the rigorous dredging activity conducted during the study, no more than approximately 25% of the market-size oysters were removed. This low removal rate and the likely growth of some submarket-size oysters into market size during the study prevented a measurable reduction in market-size oysters from taking place.

One result of the low dredge efficiency during fishing operations is the constant redistribution of shell and oysters without retrieval to the fishing vessel. Presumably, this redistribution should result in burial of some portion of the oyster population for some period of time. Oysters are well known for being able to withstand prolonged periods of anoxia that might occur with burial (Shumway 1982, Baker & Mann 1992), however, the time between dredging events was typically several months. Thus, an increase in mortality due to burial might have been anticipated. None was observed, indicating that the redistribution of shell and oysters must normally not result in burial so deep that oysters cannot open their valves and filter at adequate rates.

Increased recruitment is often observed on planted shell (Abbe 1988). In the same vein, the activity of fishing by turning over shell and exposing clean surfaces might increase recruitment. Our study was done during a period of low recruitment on the lower half of the Delaware Bay oyster seed beds, including New Beds, and so the results may not be generally applicable. However, re-

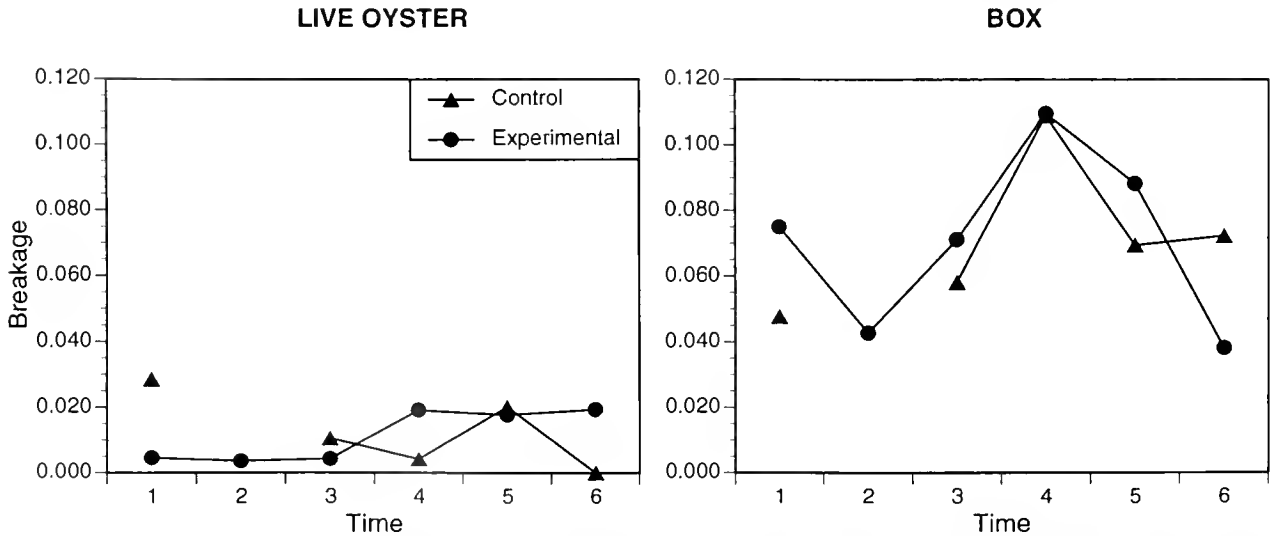

Figure 13. Time-dependent changes in the frequency of breakage of live oysters and boxes during the study. Time segments are defined in Figure 10.

peated dredging in this study did not significantly affect spat recruitment or mortality.

Taphonomic Indicators: Boxes vs. Live Oysters

The taphonomic indicators consistently showed a surprising similarity between boxes and live oysters. Ratios between live oysters and boxes for the various taphonomic indicators were normally 1 ± 0.1 (Fig. 14). Thus, seasonal changes in taphonomic condition of live oysters were followed reasonably well by seasonal changes in taphonomic condition of boxes. The implication is that most boxes are not very old, probably less than six mo. Christmas et al. (1997) observed boxes routinely surviving for several years in Chesapeake Bay. Our observations would suggest that disarticulation rates are much higher in Delaware Bay.

We observed no significant reduction in box number due to dredging, even though one might assume that dredging should result in some degree of disarticulation. Thus, the apparently short "life span" of boxes does not seem to be a function of fishing. The similarity between control and experimental sites also indicates that disarticulation rates are not significantly increased by fishing activity. The study was conducted during a time when mortality

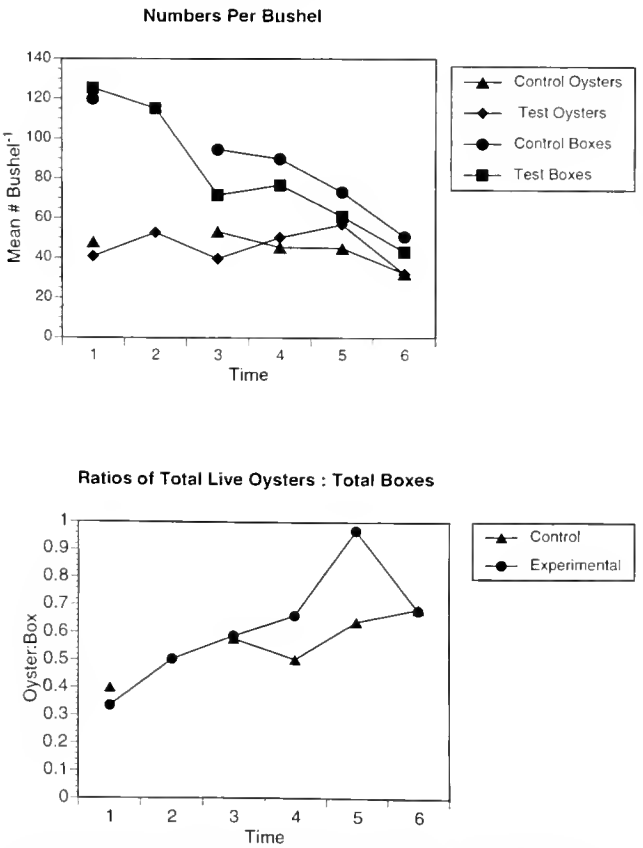

Figure 15. Time-dependent changes in the number of live oysters and boxes per bushel of shell and the ratio of live oysters to boxes during the study. The ratio is calculated as $\frac{\text{number of live oysters}}{\text{number of boxes}}$.

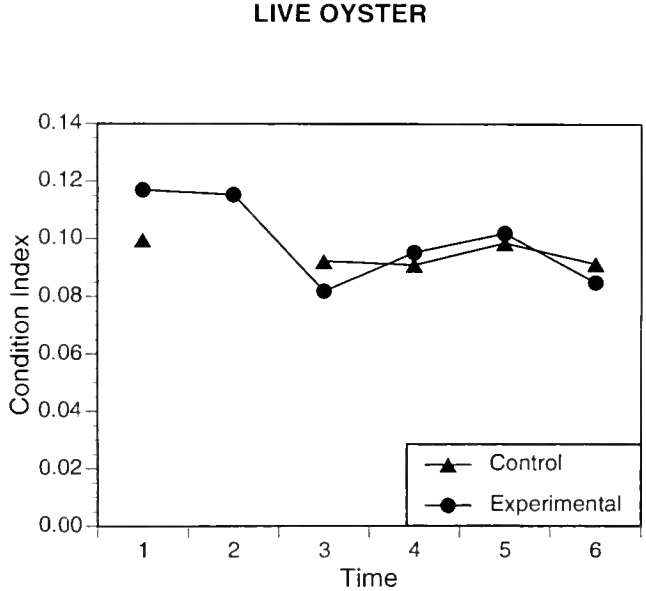

Figure 16. Time-dependent changes in condition index for live oysters during the study. Time segments are defined in Figure 10.

from *P. marinus* was high, greater than 50% of the market size population on New Beds in 2000. Thus, Dermo mortality is the likely principal source of new boxes. Boxes typically outnumbered live oysters by a factor of two at the beginning of the study (Fig. 15). Thus, disarticulation rates must average 25% or more yearly at steady state. In fact, during the study, the number of boxes decreased by a factor of about two (Fig. 15) and the live oyster-to-box ratio increased from about 0.4 to 0.7. Thus, the ongoing mortality in the oyster population imposed an increasingly large signal on the box population as the study progressed. Under these conditions, the taphonomic condition of the box population should always mirror the taphonomic condition of the living oysters to a substantial degree.

Why disarticulation rates were so high is unknown. One possibility is the high clionid activity noted during the study (Fig. 17) that may have weakened the valves of boxes and increased disarticulation rates.

CONCLUSIONS

Over a very long time, dredging may significantly influence oyster bed physiography and community structure. The reduction in the number and size of oyster clumps on fished beds is a good example. However, once the bed has become a fished bed, this study suggests that moderate dredging that results in a yearly swept area of no more than four times the area of the bed is unlikely to result in significant further impact on the oyster populations living there. In this study, no evidence was obtained for increased mortality, decreased growth or recruitment, or increased *P. marinus* disease pressure from repeated dredging. This is a considerably different result from the observed impact of bottom fishing on some soft-bottom bivalves (e.g., Witbaard & Klein 1994) and certainly arises out of the more robust nature of the oyster shell combined with the oyster's relatively rapid capability for shell repair.

A question could be raised as to the degree of impact necessary to effect a measurable change in oyster population attributes. Due to the nonlinearity of most taphonomic processes (Callender et al., in press; Staff et al., in press) and most physiological processes (e.g., Powell et al. 1996, Ford et al. 1999), statistical modeling based on the results of this study is unlikely to provide accurate insight. A study in which cumulative impact was substantially increased over the 300 to 600 m^2 per 10 × 10-m square obtained in this study would be necessary. However, since the cumulative dredging impact in this study already exceeds by a considerable measure the impact of today's fishery in Delaware Bay, our results are sufficient to conclude that dredging at present levels of exploitation is relatively benign in its influence on oyster population health and productivity.

ACKNOWLEDGMENTS

Special thanks to Scott Bailey who captained the two dredge boats, the *F/V Miss Kathy* (one dredge) and the *F/V Britt Ann Marcher* (two dredges) used for the ten 8-h dredging events (5 days, two experimental sites). Special thanks also to Royce Reed and the NJDEP for maintaining the corner markers on the four sites during the study. We thank Larry Hickman, Captain of the *Howard W. Sockwell*, and Bivalve Packing for help in sample collection, and Meagan Cummings for help in data collection and analysis.

A FISHERIES MODEL FOR MANAGING THE OYSTER FISHERY DURING TIMES OF DISEASE

JOHN M. KLINCK,[1] ERIC N. POWELL,[2] JOHN N. KRAEUTER,[2] SUSAN E. FORD,[2] KATHRYN A. ASHTON-ALCOX[2]

[1]*Center for Coastal Physical Oceanography, Crittenton Hall, Old Dominion University, Norfolk, Virginia 23529;* [2]*Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Ave., Port Norris, New Jersey 08349*

ABSTRACT Setting the yearly allocation for a fished stock is always an uncertain endeavor. Populations suffering significant mortality from disease require particularly careful management. Disease mortality is not a standard component of fisheries models, however. Here, we develop a model for the management of fished oyster populations in which disease mortality is a controlling influence. The model requires a quantitative estimate of abundance by size class, some knowledge about growth rates to establish the size range recruiting into the fishery, and an estimate of the anticipated natural mortality rate. The latter is of considerable consequence because small changes in mortality rate effect large changes in predicted outcomes. The model permits investigation of scenarios that include a range of allocations, timing of fishing seasons, variation in fishing efforts within seasons to establish a preferred harvest level, variations in the distribution of fishing among beds to minimize overharvesting of disease-affected beds (area management), and rebuilding plans to increase total stock abundance after epizootic mortality or periods of overharvesting. The model is sufficiently general that it can be applied to any commercial shellfish species. Simulations show that appropriate timing of the fishing season with respect to the timing of disease mortality can more than double the yearly allocation to the fishery. Some harvested animals would otherwise have died from disease. Besides disease, the other model parameter that most affects simulation outcome is the abundance of submarket-size oysters that can be expected to recruit to the fishery in the simulated year. Population stability is strongly determined by the number of recruits available to replace the deaths that decimate the market-size population each year. The number of recruits is a function of survivorship in previous years, but also the anticipated growth rate that defines the size range of oysters at the beginning of the fishing year that can be expected to recruit to the fishery. This modeling exercise points to the critical need to understand population dynamics and survival of size classes below market size that are not often the targets of investigatory activities.

KEY WORDS: fisheries models, management, mortality rate, disease, Dermo, stock assessment

INTRODUCTION

At one time, Delaware Bay was one of the leading producers of American oysters (*Crassostrea virginica*) in the United States (Mackenzie Jr. 1996, Ford 1997). Like many other East coast estuaries, diseases, principally caused by the protozoan parasites *Haplosporidium nelsoni* and *Perkinsus marinus*, have seriously reduced oyster abundance and, consequently, the oyster industry has declined (Ford 1997, Fegley et al. 1994). The diseases have also necessitated changes in the way oysters are harvested. At one time, oystermen transplanted oysters from upbay seed beds downbay to leased grounds for grow-out. These higher-salinity leased grounds have fallen into disuse or production on them has been seriously curtailed by the high rates of disease mortality of oysters planted there. Consequently, new approaches have been proposed (Ford & Haskin 1988, Ford 1992, Powell et al. 1997). One of these options is to concentrate all phases of production on the upestuary seed beds where lower salinity limits disease-produced mortality, at least to some extent. Concentrating all phases of production on the seed beds necessitates increased vigilance by oyster managers (HSRL, 2000, 2001).

In Delaware Bay, the highest quality oysters are produced naturally on the lower third of the seed beds (Fig. 1). Consequently, in recent years, oyster production has focused on two production schemes: (1) direct marketing of oysters produced on these lower seed beds, essentially a wild fishery; and (2) transplanting oysters downbay to these lower seed beds with subsequent recapture for sale. Upbay oysters tend to be smaller and of lower market quality. Both conditions improve within a few months to a year when moved downbay (Powell et al. 1997). One necessary consequence of both of these approaches is a need to estimate the total allowable catch (TAC) from the seed beds each year, essentially the setting of a yearly allocation for transplant downbay and for direct marketing (HSRL, 2000, 2001).

The problem of setting an allocation is an interesting one because oyster diseases produce high natural mortality rates that are relatively unpredictable from one year to the next (Jordan 1995, Powell et al. 1996, Brousseau et al. 1998). This obviates the possibility managing under standard fisheries guidelines that focus on biomass at maximum sustainable yield (B_{msy}) and normally define B_{msy} as one-half of the carrying capacity ($K/2$) (May et al. 1978, Applegate et al. 1998, Restrepo et al. 1998). Disease mortality is not a standard component of fisheries models. Even in cases where natural mortality may be principally caused by disease, a standard fisheries modeling approach has been used (Allen, 1979). Nor is it clear that K is a concept that can be applied straightforwardly to populations whose dynamics are inherently controlled by disease. Population models addressing the issue of carrying capacity and disease, such as described by Heesterbeek and Roberts (1995) and Swinton and Anderson (1995), have not yet been applied to marine species, although the need for doing so continues to increase (Harvell et al. 1999).

What seems clear is that oyster populations are well below pre-disease levels in many Mid-Atlantic bays today (Andrews 1988, 1996, Gottlieb & Schweighofer 1996, Ford 1997) and that recovery to pre-disease levels is unlikely with the continued presence of disease. The purpose of this contribution is to develop a model for the management of fished oyster populations in which disease mortality is a controlling influence and for which management options cannot be described in terms of B_{msy} and K. We use, as an example, the oyster populations and oyster fishery of Delaware Bay (Fig. 1). Because many of the same issues exist for a

Figure 1. Location of the oyster seed beds in Delaware Bay referred to in this report.

number of commercial shellfish species where disease mortality is significant (e.g., Sousa 1991, Miller & Lawrenz-Miller 1993, Moyer et al. 1993, Park et al. 1999, Bower et al. 1999, Sunila et al. 1999), this modeling approach may have a much wider applicability.

The Model

The modeling exercise begins with the familiar equation

$$\frac{dN}{dt} = -ZN \tag{1}$$

that describes a change in abundance (N) as a function of mortality rate (Z). Equation (1) is solved under the boundary condition that $N = N_0$ at $t = 0$:

$$N(t) = N_0 e^{-Zt} \tag{2}$$

where t is time in days. For a fished species, total mortality rate, Z, can be decomposed into a natural mortality rate, m, and a mortality rate due to fishing, f: $Z = m + f$. Thus,

$$N(t) = N_0 e^{-(m+f)t}. \tag{3}$$

Application of equation (3) to management of the Delaware Bay oyster industry faces a number of serious problems, all of which stem from the time-dependency of the two mortality rates. The first of these problems is that the natural mortality rate, m, is principally determined by Dermo disease. Dermo disease intensifies during the summer months, generally culminating in increased mortality in late summer and fall (Andrews 1988, O'Beirn et al. 1994, Powell et al. 1996, Oliver et al. 1998, Brousseau & Baglivo 2000). Thus, m is not constant over the year. Secondly, the fishery does not impact the oyster population equivalently throughout the year. Typically, a spring and a fall season are separated by a summer period when harvesting is minimal and fishing normally ceases during the winter (HSRL, 2000, 2001). Equation (3) assumes that the two mortality processes, fishing (f) and natural mortality (m), covary such that neither varies seasonally or, if they do vary seasonally, both rise and fall proportionately during the year. This is patently not the case for the natural mortality rate of most estuarine shellfish and rarely the case for fishing mortality for most estuarine shellfisheries. Finally, some portion of fishing mortality is likely to be compensatory because some of the oysters harvested during the spring and early summer would have died from Dermo disease in the following late summer and autumn. Whether different sources of mortality are additive or compensatory is a critical issue in the population dynamics of species where mortality from parasitism and disease is important (Jakobsen et al. 1988, Meißner & Bick 1997, see also Thomas & Kunin 1999). In this case, knowing how the two sources of mortality, from disease and fishing, interact may be particularly important because one of them, fishing, can be manipulated in time to maximize the compensatory component and, consequently, reduce the effect of the fishery on the stock.

A more complex formulation than equation (3) is needed to address issues of seasonality in mortality rates and the interaction between mortality rates. The following model is designed to resolve the issue of time-dependent mortality rates and compensation between mortality rates, while retaining the desirable characteristic of allowing an analytical solution. For simplicity in model construction, we have chosen to define the process of recruitment into the fishery as a rate, like mortality. This requires that the rate of recruitment into the fishery be a function of the number of market-size animals present; however, a standard stock-recruitment relationship (Hilborn & Walters 1992) is rarely, if ever, present (Loosanoff 1966, Hofstetter 1977, Hofmann et al. 1992, Whitlatch & Osman, 1994). In the Delaware Bay fishery, market-size oysters are typically ≥76 mm in length, although no regulatory size limit is in force. Oyster growth rates vary within and between bays along the East and Gulf coasts (O'Beirn et al. 1996, Mackenzie & Wakida-Kusunoki 1997, Dittman et al. 1998). On the direct-market beds of Delaware Bay, growth rates are such that oysters of about 63.5–76 mm in January, defined as submarkets, can be expected to recruit to the fishery in the coming year. Because no regulatory size limit exists and oysters recruit to the fishery in an uneven and unpredictable way (non-knife edge), we resolve the issue of dependency of recruitment on the abundance of market-size oysters by defining recruitment rate such that the recruits reach market size on the first day of the year. This permits the dependency to be artificially defined at the beginning of each simulated year by appropriate choice of recruitment rate (R) with respect to market-size abundance (N).

Accordingly, equation (3) describing the change in abundance over time is expanded to

$$\frac{dN}{dt} = [-Z(t) + R(t)]N \tag{4}$$

where Z represents the sum of a series of time-dependent mortality rates. For the purposes of the present application to management of the oyster fishery in Delaware Bay, Z includes f_1, the fishing rate during the first (spring) season, f_2, the fishing rate during the

second (autumn) season, and m_o the non-fishing mortality rate (mainly Dermo-produced during late summer and early fall). Each of these processes is active over only part of the year. Hence, for market-size oysters

$$\frac{dN}{dt} = [-f_1(t) - f_2(t) - m(t) + R(t)]N. \tag{5}$$

The general solution for this model is

$$N(t) = N_o e^{A(t)}, \tag{6}$$

where N_o is the number of market-size oysters present at the beginning of the year and

$$A(t) = \int_0^t [-f_1(\tau) - f_2(\tau) - m(\tau) + R(\tau)]d\tau. \tag{7}$$

The population is invariant over a year if $A(T) = 0$, where $T = 1$ year (or 365 days since t is in days). When $A(T) = 0$, the various removal processes just match recruitment into the fishery over the year.

The effect of each term included in the right side of equation (7) can be calculated by integrating the right side of equation (5) with respect to that term. For example, the cumulative number of oysters per area removed by fishing during the spring season ($O_{f_1}(T)$) is

$$O_{f_1}(T) = \int_0^T f_1(\tau)N(\tau)d\tau. \tag{8}$$

The structure of the various terms is required to proceed. First let recruitment R be an impulse or delta function at the beginning of the year, or

$$R(t) = R_o\, \delta(t - \epsilon), \tag{9}$$

where R_o is the total recruitment rate and ϵ is a small number to have recruitment occur shortly after $t = 0$. If the recruitment is expected to double the number of oysters at the beginning of the year, then $R_o = \log_e 2$. This impulsive form resolves the issue of dependency of recruitment into the fishery on N.

Each of the other terms is modeled with a box-like structure so that the process turns on and off at certain times. That is, each term turns on once and then turns off (Fig. 2). This formulation allows more than one process to be on at a time, so the model is completely general. Each term has the form

$$B(t : t_1, t_2) = \frac{1}{2}\left[\tanh\left(\frac{t - t_1}{a}\right) - \tanh\left(\frac{t - t_2}{a}\right)\right]. \tag{10}$$

The 'box' function described by equation (10) has the value one-half at the times t_1 and t_2, or $B(t_1) = B(t_2) = 0.5$ (Figure 2). The parameter a, with units of days, controls how fast the process turns on or off. So, for small a (at $a \ll 1$), $B = 0$ before $t = t_1$, B = 1 for $t_1 < t < t_2$ and $B = 0$ after $t = t_2$ (Figure 2). For a regulated behavior, such as fishing, where seasons open and close over the course of a single day, a small a permits the process of fishing mortality to rapidly switch on and off as required ($a = 0.5$ in Fig. 2). For disease mortality that waxes and wanes over a longer period of time, a larger a permits the rate to increase and decrease slowly over a period of weeks ($a = 10$ in Fig. 2).

The time integral of the box function is required to get the solution; that is, to get $A(t)$, so

$$\begin{aligned} BI(t; t_1, t_2) &= \int_0^t B(\tau)d\tau \\ &= \frac{a}{2}\left[\log\cosh\left(\frac{t - t_1}{a}\right) - \log\cosh\left(\frac{t_1}{a}\right)\right. \\ &\quad \left. - \log\cosh\left(\frac{t - t_2}{a}\right) + \log\cosh\left(\frac{t_2}{a}\right)\right]. \end{aligned} \tag{11}$$

Although it is not clear from this formula, $BI(t; t_1, t_2)$ $(t \gg t_2) = t_2 - t_1$. That is, the integral of $B(t; t_1, t_2)$ beyond the end of the 'box' defined by t_1 and t_2 is just the time the process is switched on, $t_2 - t_1$ (in days).

The various sources of mortality are represented as

$$(f_1, f_2, m) = (f_{10}, f_{20}, m_0)B(t; t_1, t_2) \tag{12}$$

where t_1 and t_2 are different for each process. So each of the fishing and mortality processes are controlled by a constant amplitude times the 'box' function which has start and stop parameters. Furthermore, the steady solution is constructed in parts as each of the processes can be integrated in time as

$$\int_0^t (f_1, f_2, m)d\tau = (f_{10}, f_{20}, m_0)BI(t; t_1, t_2). \tag{13}$$

The recruitment function used to calculate total recruitment, $\hat{R}_o$, is simple to integrate because of the pulse-like behavior:

$$\int_0^t R(\tau)d\tau = \int_0^t R_o\, \delta(\tau - \epsilon)d\tau = \hat{R}_o \tag{14}$$

as long as $t > \epsilon$. But this is always true after the first day.

Further development of the model requires establishment of a goal for the management program. One option, given the uncertainties in year-to-year variations in natural mortality that preclude evaluation of the stock abundance relative to a known value such as carrying capacity K, is to adopt the goal that market-size abundance should not decline over the year due to activities of the fishery. Stated mathematically:

$$N_{t=0} = N_{t=365}. \tag{15}$$

The condition expressed by equation (15) necessitates that the rate processes in equation (7) sum to zero [$A(T) = 0$] or

$$\hat{R}_o - f_{10}BI(T; t_1, t_2) - f_{20}BI(T; t_3, t_4) - m_0BI(T; t_5, t_6) = 0, \tag{16}$$

where t_1, t_2, t_3, t_4, t_5, and t_6 are the transition times for fishing and natural mortality. The form of the 'box' function means that each

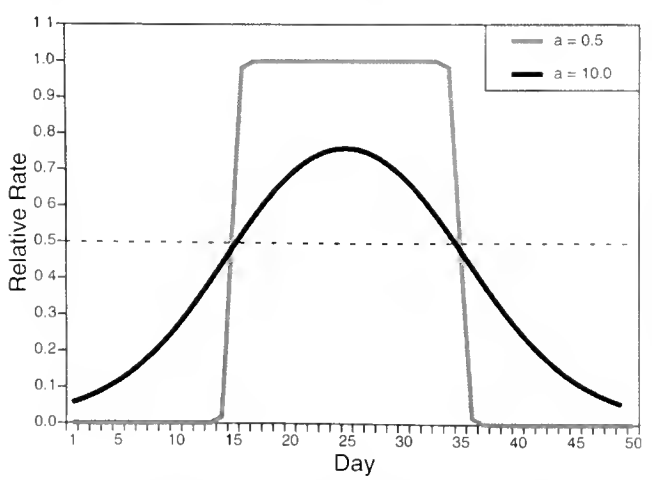

Figure 2. Examples of the time-dependent rate functions used for mortality rates (equation [10]). Grey line, the time-dependent fishing mortality rate, $a = 0.5$. Black line, the time-dependent *Perkinsus marinus* mortality rate, $a = 10$.

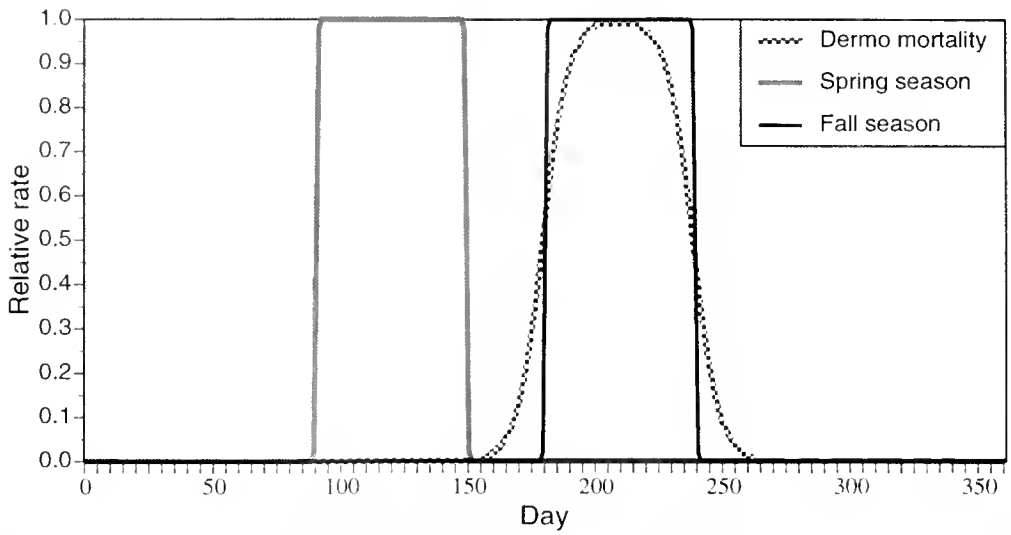

Figure 3. An example time series of mortality rates showing the two independent fishing seasons and the time of highest *Perkinsus marinus* induced mortality.

term in equation (16) reduces to the time span that each process is on times a constant amplitude. An example time series is shown in Figure 3. So, equation (16) becomes

$$\hat{R}_o - f_{10}(t_2 - t_1) - f_{20}(t_4 - t_3) - m_0(t_6 - t_5) = 0. \quad (17)$$

A little rearrangement gives

$$(t_2 - t_1)f_{10} + (t_4 - t_3)f_{20} = \hat{R}_o - (t_6 - t_5)m_0 \quad (18)$$

Equation (18) gives a relationship between the two fishery rates compared to recruitment and natural mortality.

The rest of the calculation is determined by the choice of the relationship between the two fishing mortalities. For example, suppose that the per day fishing rates for spring and fall are the same. This simply says that the daily effort and catch per unit effort are constant. In the case of the Delaware Bay oyster fishery, daily effort and CPUE (measured in terms of bushels d^{-1}) are very similar in the fall and spring and CPUE varies little between years because changes in stock abundance do not substantially influence CPUE (when measured in terms of bushels d^{-1}). (Banta et al., in press). Thus, $f_{20} \sim f_{10}$ and the fishing rates are easily estimated by:

$$f_{10} = \frac{\hat{R}_o - (t_6 - t_5)m_0}{t_2 - t_1 + t_4 - t_3}. \quad (19)$$

In some cases, such as after an epizootic, maintaining a stable population may not be desirable. In this case, the balance between recruitment and mortality established by equations (6) and (15–18) must be altered. Equation (6) becomes

$$N(t) = \frac{N_o}{\eta} e^{A(t)}, \quad (20)$$

where η is the desired ratio between the abundance of market-size oysters at the beginning of the year ($N_{t=0}$) and at year's end ($N_{t=365}$): $N_{t=0}/N_{t=365} = \eta$. Equation (20) can be rearranged to

$$N(t) = N_o e^{[A(t) - \log_e(\eta)]}. \quad (21)$$

Equation (17) then becomes

$$\hat{R}_o - f_{10}(t_2 - t_1) - f_{20}(t_4 - t_3) - m_0(t_6 - t_5) = \log_e(\eta). \quad (22)$$

Once again, letting $f_{10} = f_{20}$ provides a relationship analogous to equation (19).

$$f_{10} = \frac{\hat{R} - (t_6 - t_5)m_0 - \log_e(\eta)}{t_2 - t_1 + t_4 - t_3}. \quad (23)$$

TABLE 1.

The total number of bushels of market-size and submarket-size oysters on the Delaware Bay oyster beds in late-October, 1999, listed in bushels based on an estimated 348 market-size oysters per bushel and 499 submarket-size oysters per bushel.

Seed Bed	Market-size Oysters	Submarket-size Oysters
Transplant Group		
Low-mortality		
Arnolds	3,182	11,646
Round Island	1,954	3,847
Upper Arnolds	3,412	12,410
Medium-mortality		
Upper Middle	0	0
Middle	19,150	30,535
High-mortality		
Beadons	899	4,017
Nantuxent Point	3,047	8,691
Direct-market Group		
Medium-mortality		
Cohansey	72,936	127,380

Egg Island	462	618
Hawk's Nest	9,447	16,774
Hog Shoal	1,681	1,857
New Beds	4,840	7,626
Strawberry	1,279	2,651
Vexton	1,815	1,857

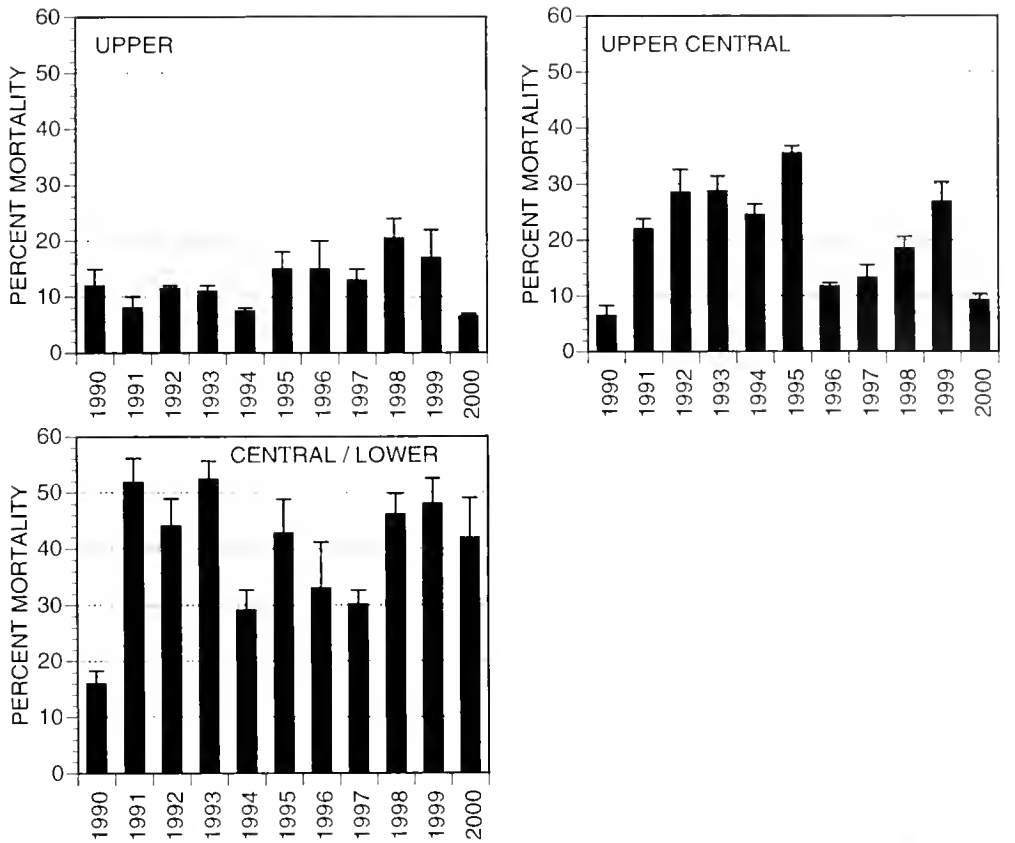

Figure 4. Yearly estimated natural mortality as a percent of total market-size abundance for the three bed groupings defined in Table 1, for the decade of the 1990s. Dermo became a significant source of mortality in 1990; as a consequence, mortality for years prior to 1990 is not included in the time series.

Data

The data come from the Delaware Bay oyster stock assessment program that has produced a yearly autumnal survey of the seed beds since the early 1950s. A stratified random sampling method is used for the survey. Each bed (Fig. 1) is divided into a series of contiguous 25-acre grids that fall into one of three strata. The strata consist of "test" areas, typifying the highest quality areas of the bed that sampling over the course of many years has shown to have a high percentage of living oysters 75% or more of the time, "high quality" areas in which oysters were abundant 25–75% of the time, and "low quality" areas in which oysters were abundant less than 25% of the time. The survey consists of about 100 samples covering the primary and most of the minor oyster beds. Each sample represents a composite of 3 one-third bushels from three randomly-directed one-minute tows within each sampled grid. The survey instrument is a standard 1.27-m commercial dredge on a typical dredge boat, the *F/V Howard W. Sockwell* in this case. Oyster abundance is quantified in terms of numbers per m^2 by correcting the raw counts obtained from the three measured (by DGPS navigation) tows by a measure of dredge efficiency (Powell et al. submitted). Data from the 2000 survey are used in model simulations (Table 1).

The seed beds were divided into three groups based on the level of natural mortality normally experienced during the 1990s (HSRL 2001). These groups will be referred to as the low-mortality, medium-mortality, and high-mortality groups (Table 1, Fig. 4). The bed groupings follow the salinity gradient, as anticipated from the importance of Dermo disease in the mortality pattern, such that the lowest natural mortality rates are on the upbay, lowest-salinity beds and the highest natural mortality rates are on the downbay, highest-salinity beds. The time series of natural mortality since 1990, when Dermo began to become an important source of mortality in Delaware Bay, is characterized by two Dermo epizootics, an extended epizootic in 1991–1995 and a shorter epizootic in 1998–1999. Percentiles of natural mortality rate were calculated from the rank-order of yearly mortalities for 1990–2000 obtained from this time series.

The oyster seed beds were also divided into two groups based on the estimated size of the smallest individual that could recruit to the fishery during one year. These sizes were 63.5 mm for all high-mortality beds (listed in Table 1) with the exception of Shell Rock and 70.0 mm for all other beds (HSRL, 2001). Finally, some beds, as shown in Table 1, are normally used in a transplant program; others are used for direct-marketing. The distinction is unimportant for this treatment, but is retained to maintain consistency with referenced sources (e.g., HSRL, 2001).

RESULTS

Compensation Between Fishing and Natural Mortality

The importance of compensatory mortality was examined using a Dermo mortality rate characteristic of epizootic conditions on the high-mortality beds (Figure 4): 0.5 yr^{-1}. Simulations were run for cases with two fishing seasons, the first opening and closing before

P. marinus reaches levels capable of generating mortality in the population and the second varying in its timing with respect to the time period of highest mortality from disease (Table 2). Simulations were run under the provision of no net change in market-size abundance over the year. Values used for the simulations were the sums of the estimated abundances of market-size and submarket-size oysters for the high-mortality direct-market beds (Table 1). In past years, these beds have supported the vast bulk of industry effort in Delaware Bay (Banta et al., in press).

Appropriate timing of the fishing season with respect to the timing of disease mortality can more than double a seasonal allocation to the fishery under the constant abundance scenario (Table 2). In the twenty simulations provided in Table 2, the highest yearly fishing allocation is 43,261 bushels. The lowest allocation is 33,969 bushels, about 20% less than the highest value. Differences in allocation often reach 50% within an individual fishing season. For example, in the first set of simulations in Table 2, the second fishing season was translated in time with respect to the timing of Dermo-induced mortality. Setting the second fishing season prior to the time of greatest disease mortality provides an allocation of 18,575 bushels. Setting the season after disease mortality ceases provides an allocation of 9,361 bushels. In each of these cases, population abundance at the end of the year is the same. Not surprisingly, varying the timing of disease mortality relative to a designated fishing season, examples of which are shown in the second group of simulations in Table 2, has a similarly profound effect on the yearly allocation.

In Delaware Bay, the oyster season normally opens in early April. Many times, the season has been split into two parts, one from April to June and one from September to November. An alternative is one long season beginning in April and extending into the summer or early autumn. To the extent that this season terminates prior to the late summer rise in disease mortality, the yearly allocation will increase over the alternative of a fall season. However, as the summer season begins to overlap the period of highest disease mortality, the yearly allocation will decrease as some oysters, otherwise harvestable, succumb to disease. An extreme example in which the fishing season is varied such that more and more of the season coincides with the time of greatest disease mortality is shown in the third group of simulations in Table 2. In this case, disease mortality occurs for a short, but intense, time in late summer. Total lost allocation reaches about 16% when the fishing season extends into and after the season of most intense natural mortality.

Historically, the fall harvest has obtained a higher market price. Hence economic issues encourage harvesting after Dermo disease has waned. However, this strategy minimizes the yearly allocation. Simulations in Table 2 suggest that the per-bushel dock-side price must at least double to compensate for the reduction in yearly allocation in epizootic years when the rate of natural mortality is high. A doubling of price is, in fact, rarely achieved, suggesting that the attraction of the higher market price in the fall is more often than not false economics in the oyster industry in these years. Harvest and, probably, dock-side value is maximized by concentrating the fishery, to the extent possible, prior to the time that disease mortality increases in late summer.

TABLE 2.

The estimated yearly allocation for spring and autumn fishing seasons during a year when 50% of the market-size oysters succumbed to Dermo disease. Day 1 was set at January 1. Data are presented in bushels. One bushel ~37 L and contains approximately 348 market-size oysters.

Solid lines show the timing of the two fishing seasons. Dashed line shows the timing of Dermo mortality.

Variation in Disease Mortality Rate

Timing of disease mortality varies from year to year and is often difficult to measure in a timely fashion for near-real-time re-evaluations of management decisions. Varying the duration of disease-mortality from 60 to 120 days, as shown in simulation sets 1 and 4 in Table 2, has only a minor influence on cumulative yearly allocation, however, as long as the yearly natural mortality rate does not change. The daily rate is lower in the case of the longer time course, but the cumulative mortality integrated over the year is about the same.

Small variations in the natural mortality rate typically have profound consequences in fisheries models (Clark 1999), and this model is no exception. The yearly loss to Dermo disease is determined by a number of factors, including temperature, salinity, food supply, and the history of disease within the populations, that determine late summer and fall infection intensity (Hofmann et al. 1995, Powell et al. 1996, Cook et al. 1998, Soniat et al. 1998). Variation in the rate of Dermo-induced mortality significantly affects the yearly allocation estimated by the model (simulation set 1, Table 3). For example, the yearly allocation more than doubles with a decrease in natural mortality rate from 0.5 yr^{-1} to 0.3 yr^{-1}. This range of natural mortality rates is routinely observed in Delaware Bay (Fig. 4). Not surprisingly, the significance of compensatory mortality in determining the preferred timing of the second fishing season declines at low natural mortality rates (simulations sets 1, 2, and 3, Table 3).

The precautionary approach to fisheries management (FAO, 1995, Restrepo et al. 1998; see also Francis & Shotton 1997) would dictate the choice of a relatively high natural mortality rate in forecasting yearly allocations, perhaps 0.5 yr^{-1} for Delaware Bay. Variation in the timing of the fall fishing season significantly affects the yearly allocation, a difference of about 8,000 bushels in the simulations presented in Table 3. In contrast, even a small drop in natural mortality rate, from 0.5 yr^{-1} to 0.4 yr^{-1}, increases the allocation by about 10,000 bushels. An increase to 0.6 yr^{-1} essentially eliminates the yearly harvest. Thus, the model, and the population, are very sensitive to year-to-year variations in natural mortality rate. Precautionary management designed to minimize the likelihood of an underestimate in natural mortality rate is one consequence of this sensitivity. Increased predictability in the time course of Dermo disease, permitting a less conservative choice of natural mortality rate, would substantially increase the yearly allocation.

Influence of Spatial Variations in Natural Mortality

Spatial changes in the rate of natural mortality, as exist along the salinity gradient, may exert a significant influence on the estimated yearly allocation. Is this variation important in the practical context of management decision-making? The Delaware Bay oyster beds were partitioned into three groups according to the long-term average rate of natural mortality, the principal source of which is *P. marinus* infection. Yearly allocations to the oyster industry were evaluated for each of the three bed groups under a

TABLE 3.

The estimated yearly allocation for spring and autumn fishing seasons as a function of natural mortality rate for three different timings for the autumn fishing season. Day 1 was set at January 1. Data are presented in bushels. One bushel ~37 L and contains approximately 348 market-size oysters.

Solid lines show the timing of the two fishing seasons. Dashed line shows the timing of Dermo mortality.

range of natural mortality rates that covered the range observed in these bed groups during the 1990s. For ease of comparison, the same oyster abundances were used for each bed group. This abundance was the 2000 abundance for the high-natural-mortality group (Table 1).

Not surprisingly, a much higher allocation was available for the low-mortality beds than for the high-mortality beds in these simulations (based on equivalent abundances between groups) (Figure 5). As before, the yearly allocation declined as natural mortality increased for each bed group. The range of allocations across the observed range of yearly mortality rates, a range that is assumed to document the range of anticipated mortality rates for a coming year, was much larger for the high-mortality group than for the other two groups.

In practice, the fishery operates principally on the high-mortality beds, hence the use of these abundance values in the simulations shown in Figure 5. A factor of two exists between the highest and lowest allocations for these beds, depending on the natural mortality rate that might occur in any given year. Obviously, errors in the prediction of natural mortality rate are most grave for this group. In fact, if stable market-size abundance is the desired outcome, taking the median rate of natural mortality for the decade of the 1990s for the low- and medium-mortality groups as the value for the coming year would introduce no more than about a 12% error in achieving this goal on these beds, even if natural mortality rate approached either the highest or lowest recorded values. In contrast, the error introduced for the high-mortality group would exceed 30%. Thus, increased levels of natural mortality increase the need for a precautionary approach to stock management given the limited ability at present to predict the course of Dermo disease (Powell et al. 1996, Soniat & Kortright 1998). For the high mortality group, use of the 64*th* or 75*th* percentile would seem appropriately conservative.

Influence of Variations in Growth Rate or Pre-recruit Abundance

Variation in the number of recruits into the fishery in a given year is also important. The premise of the model is to manage the fishery under the proviso of no net change in market-size abundance. Accordingly, the allocation is a function of the availability of new recruits and the natural mortality rate. The number of new recruits is controlled not only by settlement and recruitment into the population and subsequent survival of juveniles, but also by the yearly growth rate that establishes the smallest-sized oyster anticipated to recruit to the fishery during the season. Because the number of oysters typically declines in the larger size classes, slower growth can have a dramatic effect on yearly allocation by reducing the number of new recruits.

The simulations shown in Figure 5 were based on the assumption that oysters 63.5–76 mm in size recruit to the fishery in a given year (market size, ≥76 mm). This is a growth rate typical of the higher-salinity oyster beds in Delaware Bay. Growth rate slows upbay. The equivalent simulations are shown for the case where oysters 70–76 mm are assumed to recruit to the fishery during the season in Figure 6. The difference in allocation is based on the observed number of oysters in these two size-classes on the high-mortality beds in 2000. About 47% of the oysters in the 63.5–76-mm size-class were ≥70 mm in size.

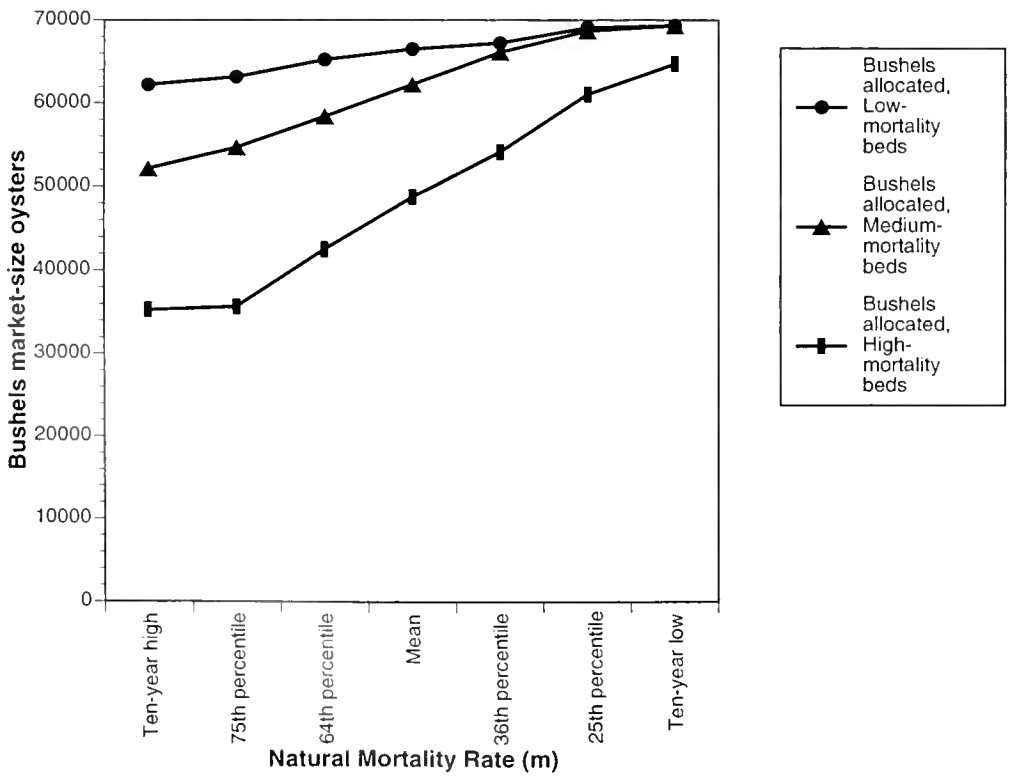

Figure 5. Yearly allocation (in bushels) for various rates of natural mortality (principally caused by *Perkinsus marinus*). Simulations were run for three groups of beds characterized by low, medium and high rates of natural mortality and for the range of natural mortality rates observed during the decade of the 1990s for these beds (Figure 4). In each case, the fishing season was initiated on day 90 and ceased on day 288 (the 2001 fishing season for New Jersey). *Perkinsus marinus*-mortality occurred between days 180 and 300 at the yearly rate shown in Figure 4. Oysters 63.5–76 mm were assumed to recruit to the fishery.

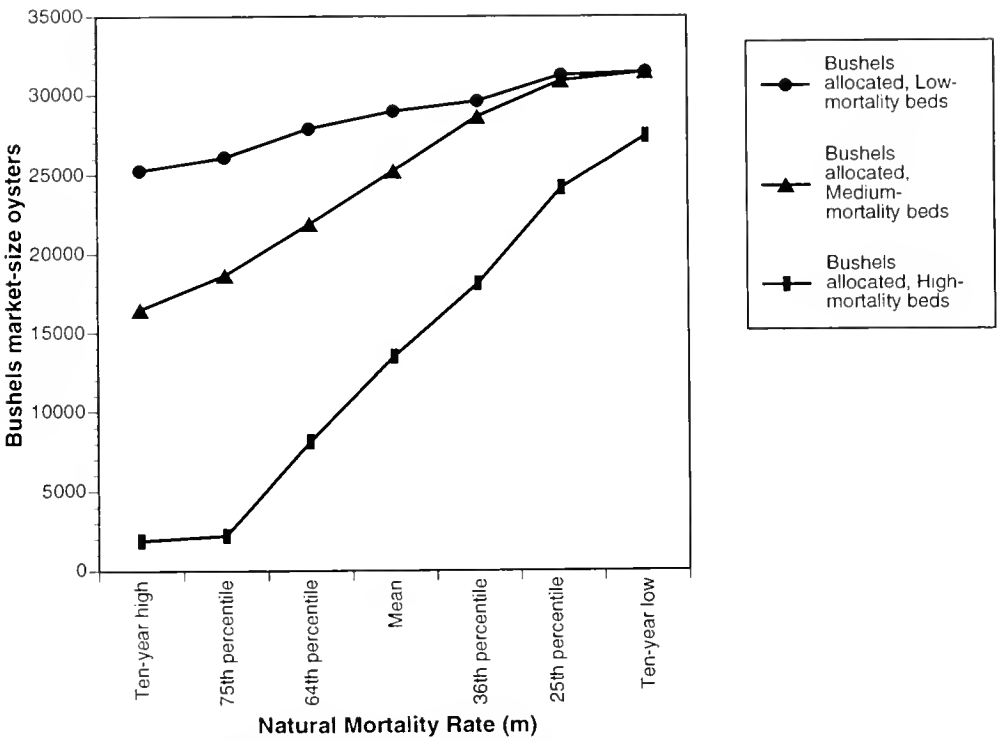

Figure 6. Yearly allocation (in bushels) for various rates of natural mortality (principally caused by *Perkinsus marinus*). Simulations were run for three groups of beds characterized by low, medium and high rates of natural mortality and for the range of natural mortality rates observed during the decade of the 1990s for these beds (Figure 4). In each case, the fishing season was initiated on day 90 and ceased on day 288 (the 2001 fishing season for New Jersey). *Perkinsus marinus*-mortality occurred between days 180 and 300 at the yearly rate shown in Figure 4. Oysters 70–76 mm were assumed to recruit to the fishery.

A reduction in the number of recruits has two significant effects. First, the total yearly allocation is significantly lower under the "slow-growth" assumption (compare Figs. 5 and 6). In addition, the range in allocation is increased when evaluated across the range of natural mortality rates observed during the decade of the 1990s. For the high-mortality beds that are most sensitive to this effect, the allocation estimated from the median rate of natural mortality for the decade of the 1990s is now a factor of 2 different from the extreme values rather than the ~30% difference observed with the higher growth rate in Figure 5. As growth slows, the importance of an accurate estimate of anticipated natural mortality rate increases and, as a practical matter, the more precautionary must be the management evaluation prior to the season.

Post-Epizootic Population Recovery

Natural mortality rates during Dermo epizootics may exceed 0.7 yr^{-1} (Mackin 1959, Andrews 1988, Powell et al. 1996). Consequently, oyster population abundance typically declines significantly during epizootic years. Management of the oyster resource might include rebuilding stocks after an epizootic. Management goals might include a return to the long-term average population level or some higher level (e.g., 75*th* percentile).

In Delaware Bay, 2000 end-of-year weighted-mean oyster abundance (calculated as # $\geq$ 76 mm + 0.5 × #63.5 – 76 mm) was near the decadal average weighted-mean oyster abundance (1989–2000) and about 67% of the decadal 75*th* percentile weighted abundance (Fig. 7). Thus, a one-year return to the 75*th* percentile weighted abundance would require an end-of-year ratio of $N_{2001}/N_{2000} = 1.50$.

Figure 8 shows the relationship between fishery allocation, natural mortality rate, and a desired degree of increase (or decrease) in market-size abundance at year's end. The 2000 allocation for Delaware Bay was 40,000 bushels for the entire bay (all beds), a low level required by the ongoing Dermo epizootic at that time. Approximately the same allocation could be achieved in 2001 just on the high-mortality beds, under the management goal of no net change in oyster abundance (Fig. 8, upright triangles). This option exists because a significant increase in juvenile oyster abundance occurred in 2000 that dramatically increased the number of new recruits available to the fishery in 2001 (Fig. 9). However, because the number of bushels available for harvest on the medium-mortality beds upbay was about 60,000 bushels (HSRL 2001) an opportunity would exist to rebuild population abundance on the high-mortality beds and still increase the yearly allocation. Figure 8 shows that rebuilding to half of the 75*th* percentile abundance goal ($N_{2001}/N_{2000} = 1.24$) can be accomplished even at a relatively high natural mortality rate, if the allocation on the high-mortality beds is reduced to about 20,000 bushels. Reaching the 75*th* percentile weighted abundance goal is achievable if the yearly allocation on these beds is limited to about 8,000 bushels (Fig. 8). Even higher abundances could be achieved; however, only if the natural mortality rate is at or below the long-term mean. Thus, recovery from the 1998–1999 epizootic with a return to above average oyster abundances could be accomplished in one year even under the precautionary management assumption that natural mortality rates will approach the 75*th* percentile of the decadal time series.

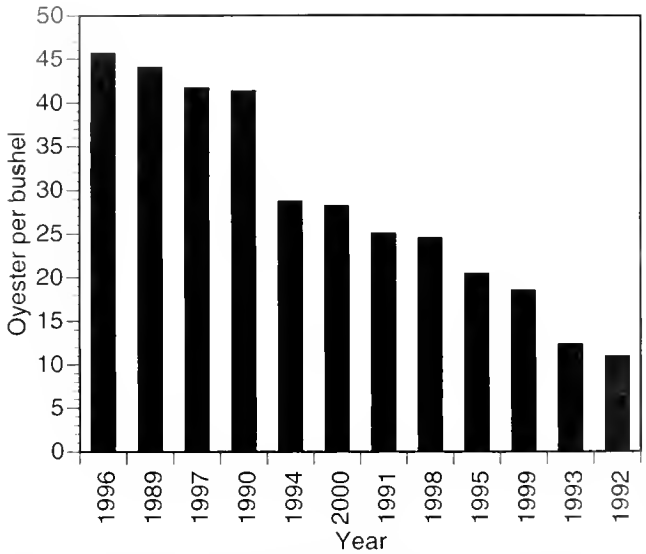

Figure 7. Rank-order of oyster weighted-mean abundance (calculated as # ≥76 mm + 0.5 × # 63.5–76 mm) for the high-mortality Delaware Bay oyster beds for 1989–2000.

DISCUSSION

Setting the yearly allocation for a fished stock is always an uncertain endeavor. Choice of the natural mortality rate is critical in most fisheries models. Populations suffering significant mortality from disease, particularly those where year-to-year changes in mortality rate cover a wide range, require particularly careful management. Unfortunately, routinely-used fisheries models do not consider mortality from disease.

Compensatory mortality is frequently observed in populations where disease mortality is significant. Some animals dying in other ways would otherwise have died from disease. In a commercial species, fishing mortality is an important additional source of mortality and compensatory processes should be important. Thus, a fisheries model developed to evaluate a diseased population must be capable of resolving compensatory mortality originating from the timing of the various sources of mortality during the year.

The model presented here permits the evaluation of compensatory processes, thereby giving guidance to appropriate timing of fishing seasons for maximizing yield. In some cases, the economic attraction of a fall harvest may be offset by the decreased yield available to the fishery. An earlier season permits a higher harvest because some of the animals taken by the fishery would subsequently be lost to the population through disease.

Although a number of shellfish models exist (Kobayashi et al. 1997, Powell et al. 1997, Dowd 1997), few fisheries models tailored specifically to shellfish exist (e.g., NEFSC, 2000a, 2000b). Fisheries models require a forward prediction of abundance under a chosen natural mortality rate m. However, small changes in mortality rate effect large changes in predicted outcomes. The present model is no exception. Outcomes are strongly influenced by the chosen yearly mortality rate. Accordingly, the accuracy of

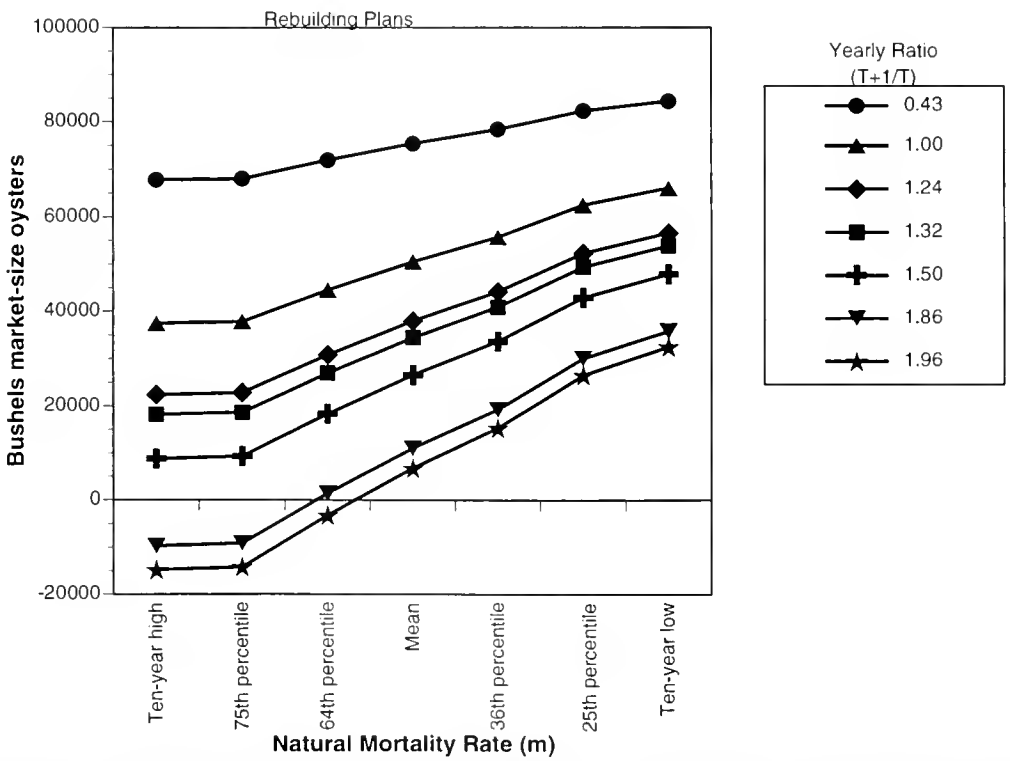

Figure 8. Yearly allocation (in bushels) for various rates of natural mortality (principally caused by *Perkinsus marinus*). Simulations were run for the high-mortality beds over a range of natural mortality rates observed during the decade of the 1990s (Figure 4). Each simulation was run to produce a desired change in market-size oyster abundance over the year, calculated as $N(T+1)/N(T)$. In each case, the fishing season was initiated on day 90 and ceased on day 288 (the 2001 fishing season for New Jersey). *Perkinsus marinus*-mortality occurred between days 180 and 300 at the yearly rate shown in Figure 4. Oysters 63.5–76 mm were assumed to recruit to the fishery. Negative numbers indicate cases where an insufficient number of new recruits was available to meet the demands of the rebuilding program.

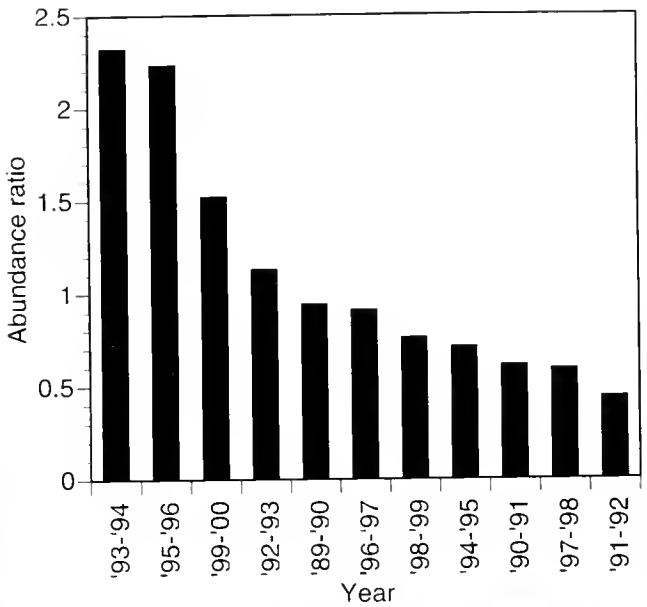

Figure 9. Rank-order of the year-to-year change in oyster weighted-mean abundance (calculated as # ≥76 mm + 0.5 × # 63.5–76 mm) for the high-mortality Delaware Bay oyster beds for 1989–2000.

forward prediction is controlled, in part, by the accuracy at which the disease process can be predicted in oyster populations.

Besides disease, the other model parameter that most affects the outcome of simulations is the abundance of submarket-size oysters that can be expected to recruit to the fishery in the simulated year. A small drop in growth rate can dramatically alter the estimate of the yearly allocation because market-size is on the tail end of the size-frequency distribution. Thus, the definition of submarket size is critical. In addition, the abundance of submarket-size individuals establishes the resilience of the population to transient increases in disease-induced mortality and to errors in management that lead to overfishing. As the number of submarketsize oysters declines, sustainability of the population becomes less certain and the accuracy of model simulations becomes more critical. In essence, as the ratio of submarket to market-size abundance approaches 1.0, reliance on more conservative management approaches should increase.

Although the maximum life span of *Crassostrea virginica* is at least 15 yr (Lavoie & Bryan 1981), the average life span in most East and Gulf coast bays probably does not exceed four due to fishing and disease. Thus, population stability is strongly determined by the number of recruits available to replace the deaths that decimate the market-size population each year. In Delaware Bay in 2000, the number of recruits was insufficient to permit rapid recovery from the most recent *P. marinus* epizootic without conservative management measures because the epizootic resulted in lower survival of the submarket-size class, a frequent characteristic of epizootic conditions (Powell et al. 1996), and because spat settlement rates were low prior to this time interval (HSRL 2001). In 2001, conditions changed. An increase in recruits to the fishery provided an opportunity to rebuild population abundances to levels above the decadal mean, while still permitting an increase in allocation over 2000. This modeling exercise points to the critical need to understand population dynamics and survival of size classes below market size that many times are not the targets of investigatory activities (Hofmann et al. 1995).

The objective of management of the oyster fishery should be the maximization of yield under conditions that stabilize population abundance at some preferred level. What that preferred level is cannot be ascertained by the model described here. However, once that preferred level is chosen, the model presented here permits the evaluation of management scenarios targeting this objective. The model requires a quantitative estimate of abundance by size class, some knowledge about growth rates to establish the size range recruiting into the fishery in any given year, and a decision about the natural mortality rate anticipated. The latter is of considerable consequence and, so, probably should be chosen conservatively, perhaps a value at or above the long-term average. Once these data are available, the model permits investigation of scenarios that include a range of allocations, the timing of fishing seasons, and the variation of fishing efforts within seasons in order to establish a preferred harvest level for the oyster fishery. The model also supports investigation of recovery scenarios after an epizootic and the evaluation of population resiliency to future epizootics or overestimates of fishery yield. The model is sufficiently general that it likely can be applied to any commercial shellfish species, providing that the stock assessment program provides survey data adequate for the modeling exercise.

ACKNOWLEDGMENTS

Special thanks to Larry Hickman, Captain of the *F/V Howard W. Sockwell* and to Bivalve Packing for providing the *F/V Howard W. Sockwell* and logistical support for the 1999 stock survey. We thank the HSRL survey team, R.D. Barber, J.A. Gandy, and B.M. Brewster, for analysis of the 2000 survey samples and S.E. Banta, M. Cummings and A.J. Bonner for help in data analysis. This study was funded by an appropriation from the State of New Jersey to Rutgers University in support of the stock survey and associated oyster research program and by funding from the Sea Grant Oyster Disease Research Program, contract number 4-25238.

A DNA PROBE FOR TRANSCRIPTION ANALYSIS OF THE PROTEOLYTIC ENZYME CATHEPSIN B IN THE PACIFIC OYSTER, *CRASSOSTREA GIGAS* (THUNBERG, 1793)

K. M. DONALD, A. J. S. HAWKINS,* AND G. R. SMERDON

Plymouth Marine Laboratory, Centre for Coastal and Marine Science, Prospect Place, Plymouth, Devon, PL1 3DH, United Kingdom

ABSTRACT Molecular techniques have been employed to develop a probe for the proteolytic enzyme cathepsin B in the Pacific oyster, *C. gigas*. Degenerate primers were used to amplify a 450 base pair (bp) fragment of the cathepsin B gene. Deduced amino acid sequence indicates 60, 59, and 59% identity with cathepsin B from human, rat and cow, respectively. Expression of cathepsin B was detected, by RT-PCR, in both larval and adult tissues. Northern blot analysis demonstrated expression of a single transcript of approximately 2.4 kb.

KEY WORDS: proteolytic enzymes, gene expression, cathepsin B, *Crassostrea gigas*

INTRODUCTION

The continuous breakdown, replacement and/or renewal of proteins, known as protein turnover, is an essential component of metabolism, enabling development, adaptation, repair and regulation (Hawkins 1991, Ciechanover & Schwartz 1994). Nevertheless, the intensity of protein turnover varies greatly according to genetic and environmental influences, with significant consequences for growth and survival among animals generally (Hawkins & Day 1999). Comparisons between individual shellfish have shown that whole-body specific activity of the key proteolytic enzyme cathepsin B correlated with the intensity of whole-body protein turnover, and was associated with both higher energy expenditure and slower growth rate (Hawkins & Day 1996). Cathepsin B is a proteolytic enzyme belonging to the papain cysteine protease superfamily (Hasnain et al. 1993), and exhibits both endo- and exopeptidase activities (Koga et al. 1991). Mammalian cathepsins have been extensively studied, due to the correlation between cathepsin activity and cancers and brain disorders, such as Alzheimer's disease and multiple sclerosis (Bernstein 1994). In comparison, cathepsin activity in invertebrates has received comparatively little attention (Zeef & Dennison 1988).

Here, to enable future work elucidating mechanisms that regulate cellular levels of cathepsin B, we describe the development of a molecular probe to monitor expression of the cathepsin B gene in the commercially important Pacific oyster *Crassostrea gigas* at different stages of development and in different adult tissues. During development, there are "critical windows" of increased protein turnover, when major structural changes occur as *C. gigas* individuals develop into different larval forms and then metamorphose from a free-swimming planktonic larva into a sessile calcified adult. Within five to 10 hours of fertilization, a non-feeding trochophore larva is formed, which within 24 to 48 hours develops into a planktotrophic, straight-hinge veliger larva (Dekshenieks et al. 1993). Between two and three weeks PF, the larva develops a foot and a pair of eyespots. This is the pediveliger form. Once the larva reaches ~300 μm, usually after approximately 25 days PF when grown at 23°C, metamorphosis occurs. This involves a major anatomical reorganization: the velum and foot are lost, the organ systems are rearranged and the gill and adductor muscle become enlarged (Galtsaff 1964). Following metamorphosis, *C. gigas* remain benthic and undergo no further re-organization of their body plan. Proteolysis continues to maintain normal functions, such as sanitation and breakdown of degraded proteins (Ciechanover & Schwartz 1994). However we do not expect levels to be as high as in the larvae, due to substantial changes in body plan and a weight specific decrease in metabolic rate. The only exception to the relatively low levels of protein turnover expected in adult tissues may be in the gonads immediately prior and post spawning, as high energy expenditure and protein turnover is necessary for spawning to take place (Peek & Gabbott 1990).

In summary, we have used molecular techniques to develop a probe to detect transcripts of the proteolytic enzyme cathepsin B gene in *C. gigas*. We have used the cathepsin B probe to quantify cathepsin B gene transcripts at times of expected high and low energy expenditure and protein turnover, which included key points in larval development and different tissues from adult oysters.

MATERIALS AND METHODS

DNA Extraction

Crassostrea gigas individuals from Whitstable oyster hatchery were acclimated for a minimum of seven days in a system of recirculated sea water at 15°C. Following this acclimation adductor muscles were dissected from individual oysters and ground under liquid nitrogen. Fifty milligrams of the ground tissue was transferred to 500 μl extraction buffer (50 mM Tris-HCl pH8, 100 mM NaCl, 50 mM EDTA, 1% SDS). Proteinase K (50 μg) was added and the solution incubated at 55°C for 1 hour. Phenol:chloroform extraction was performed on the solution and DNA precipitated by incubation with 0.1 volumes 3M NaOAc and 2.5 volumes 100% ethanol at −20°C overnight. The precipitated DNA was harvested by centrifugation, washed in 70% ethanol and dried in a vacuum desiccator. The dried pellet was re-suspended in 500 μl TE and incubated with 5 μl RNase (10 $mg.ml^{-1}$) at 37°C for 30 minutes and then with 10 μl proteinase K (10$mg.ml^{-1}$) at 55°C for 30 minutes. A second phenol:chloroform extraction and ethanol precipitation were then performed and the DNA harvested by centrifugation. The pellet was washed in 70% ethanol, dried by vacuum desiccation and re-suspended in 500 μl TE. The purity and quantity of DNA was measured spectrophotometrically and by agarose gel electrophoresis.

PCR-Amplification

Amplification of genomic DNA was performed using 100 ng extracted DNA template per reaction. Degenerate primers were

*Corresponding author.

designed from conserved regions of the cathepsin B gene, using the sequence entries in the EMBL database and software at the Human Genome Mapping Project Resource Centre (HGMP-RC), Cambridge UK (see Fig. 1).

Cath1f: 5′-gg(a/c/t) tg(c/t) (a/c/g)a(a/g/t) ggt (a/g)g(a/c) tat-3′; Cath1r: 5′-ga(a/g) ttg gc(a/c/g/t) a(c/t)(a/c) agc cag-3′

The initial cycling parameters included a denaturation step of 92°C (5 min), followed by 35 cycles of 48°C (1 min), 72°C (1 min), and 92°C (1 min). A final annealing phase at 48°C (2 min) was followed by an extension phase at 72°C (5 min) and storage at 4°C. Due to the limited quantities of initial PCR product, a second amplification was performed with identical primers using 5 μl of the initial PCR product as template and with the annealing temperature increased to 50°C and the number of cycles reduced to 30. Aliquots of the second amplification reaction were visualized by agarose gel electrophoresis (1.2%).

Sequencing

To verify that the correct gene had been amplified, the PCR product was cloned into the *Sma*I site of pBluescript SK⁻, to produce plasmid p*CG*cathI, and sequencing was performed following the dideoxy chain termination method (Sanger et al. 1977) and using the Sequenase II sequencing kit (Amersham).

Transcript Detection

Two methods were used to detect CathB transcripts, reverse transcription (RT)-PCR and northern blotting. There are merits and drawbacks to both techniques. During RT-PCR, RNA is reverse transcribed to make cDNA, which is then amplified by PCR using gene specific primers. RT-PCR is a very sensitive technique. However it is non-quantitative and can only be used to look for the presence/absence of any expressed gene. Also, transcript size cannot be determined using RT-PCR as only part of the transcript is amplified. Northern blotting involves the hybridization of a radiolabelled probe to size separated transcripts. This technique can be used to identify transcript size and for quantitation, but is less sensitive than RT-PCR.

RNA Extraction and RT-PCR

RNA was extracted from adults and from larvae at "critical windows" in development when protein turnover was expected to be high; at one day post-fertilization the larvae is developing from the trochophore into the veliger form and around settlement the larvae changes from a free-swimming larvae to a calcified adult. At both these stages energy expenditure and metamorphosis are high. Adult tissue, dissected from six individual oysters several days post spawning, and larvae, sampled at one day PF and around settlement metamorphosis, were obtained from the Whitstable oyster hatchery. The oysters were prepared for RNA extraction by grinding the adult tissue under liquid nitrogen and homogenizing the larvae in lysis buffer. RNA was then extracted using the SV total RNA isolation system (Promega). The quantity and purity of RNA were measured spectrophotometrically and RNA quality was determined by electrophoresis.

RT-PCR was performed using 100 ng RNA as the template with the Access RT-PCR system (Promega) in conjunction with non-degenerate primers designed directly from *C. gigas* sequence data.

Cgigas.cath1f: 5′-ggt tgc aat ggt aga tat cc-3′; Cgigas.cath1r: 5′-gaa ttg gcc atc agc cag ta-3′

The Promega Access RT-PCR system uses avian myeloblastosis virus (AMV) reverse transcriptase for first strand cDNA synthesis, and the thermostable *Tfl* DNA polymerase for second strand cDNA synthesis and amplification. First strand cDNA synthesis was performed with an initial 45-minute incubation at 48°C. Following inactivation of AMV-RT by a two minute incubation at 94°C, second strand synthesis, consisting of 40 cycles of 53°C (1 min), 68°C (2 min) and 94°C (30 sec) was performed. A final extension phase at 68°C (7 min) was followed by storage at 4°C. Following the initial RT-PCR, a nested PCR reaction was performed on 2 μl product using an annealing temperature of 56°C, 30 cycles and Taq polymerase (Promega) and a new forward primer again designed from specific *C. gigas* sequence.

Figure 1. Alignment of cathepsin B sequences from (a) *Homo sapiens*; (b) *Bos taurus*; (c) *Mus musculus*; (d) *Schistosoma japonicum*; (e) *Aedes aegypti*; and (f) *Triticum aestivum*. Conserved regions are boxed; primers designed from such regions are shown in bold.

Aliquots of the amplification reaction were analysed by agarose gel electrophoresis (1.5%) to check amplification efficiency.

Northern Blotting

For the probe, an XbaI and EcoRI (Promega) fragment containing the cathepsin B sequence was excised from the p*CG*cathI plasmid by restriction digest with *Xba*I and *Eco*RI (Promega). The cathepsin B fragment was purified by agarose gel electrophoresis and extraction from the gel was performed using the Qiaex extraction kit (Qiagen). 25 ng of this extracted DNA was used for probe construction using a Prime-It II random primer labelling kit (Stratagene) and ^{32}PdATP (Amersham).

RNA totalling up to 30–100μg from larvae one day PF and around settlement and from both adult digestive gland, adductor muscle and gonads and larvae at different stages of development were analyzed using Reliant RNA gels in MOPS buffer (FMC BioProducts). RNA was electrophoresed for two hours at 3.5 volts per cm. RNA markers (Promega) were run alongside the RNA samples so the size of the CathB transcript could ultimately be determined. Following electrophoresis the markers were stained with ethidium bromide. The RNA samples were then blotted onto Hybond N+ membrane and the position of the RNA markers recorded on the membrane which was then placed at 80°C for two hours to fix the RNA to the membrane.

The Hybond N+ membrane was pre-hybridized for one hour at 42°C in 10 ml ULTRAhyb™ ultrasensitive hybridisation buffer (Ambion). ^{32}P-labelled probe was added to the membrane which was left shaking at 42°C. Following hybridization for 16 hours, the probe was removed and the membrane was washed for 2 × 5 min in 2 × SSC, 0.1% SDS at 42°C and then for 1 × 10 min in 0.1 × SSC, 0.1% SDS at 42°C. The membrane was then sealed in Saran wrap and exposed to X-ray film for three days at –80°C.

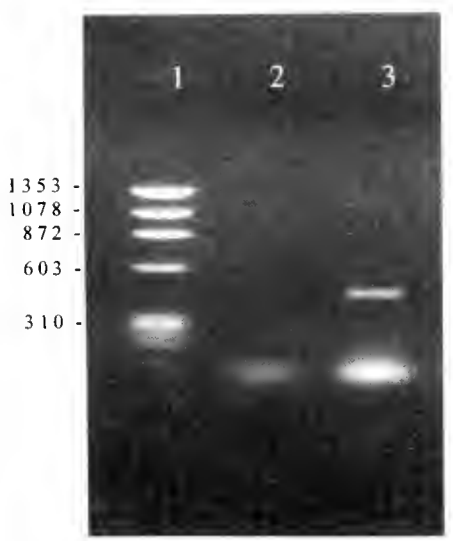

Figure 2. Amplification of cathepsin B fragment from adult *C. gigas* DNA using primers cathIf and cathIr. (PCR conditions are described in section 2.2). A total of 5 μl PCR products were analyzed on a 1.2% agarose gel. Lane 1 = ϕ×174/HaeIII size markers; lane 2 = –ve control lacking template DNA; lane 3 = template DNA extracted from adductor muscle. The sizes of the molecular weight markers are indicated in base pairs.

Figure 3. Nucleotide sequence and deduced amino-acid sequence of the cloned 450 b.p. cathepsin B fragment from *C. gigas*. Primer sequences are shown in bold.

RESULTS

Isolation of a C. gigas *Cathepsin B Clone*

Amplification of genomic DNA with degenerate primers designed from conserved regions of 3 vertebrate, 2 invertebrate and 1 plant cathepsin B nucleotide sequences (Fig. 1), resulted in amplification of a 450 bp fragment (Fig. 2).

Sequence Analysis of the C. gigas *Cathepsin B Fragment*

The nucleotide and deduced amino acid sequence of the cathepsin B clone are shown in Figure 3. As predicted from the PCR amplification, the cloned cathepsin B fragment was 450 bp long. The deduced amino acid sequence was compared with cathepsin B amino acid sequences for *Homo sapiens* (human), *Rattus norvegicus* (rat) and *Bos taurus* (cow) (Fig. 4). The *C. gigas* cathepsin B fragment showed 60% identity to *H. sapiens*, 59% identity to *R. norvegicus* and 58% identity to *B. taurus* at the amino acid level.

Expression Analysis of the Cathepsin B Gene in C. gigas

A cathepsin B transcript was detected in both adult and larval tissues after reverse transcription and two rounds of PCR (Fig. 5), indicating cathepsin B expression in both adult and larval tissues. For a quantitative but less sensitive technique, northern blot analysis was performed on a selection of adult tissue and larvae at different stages of development (Fig. 6). The probe identified a

Figure 4. Amino acid sequence comparison of cathepsin B from *C. gigas* with sequences from *Homo sapiens*, *Rattus norvegicus*, and *Bos taurus*. Amino acid residues that are identical to *C. gigas* cathepsin B are boxed.

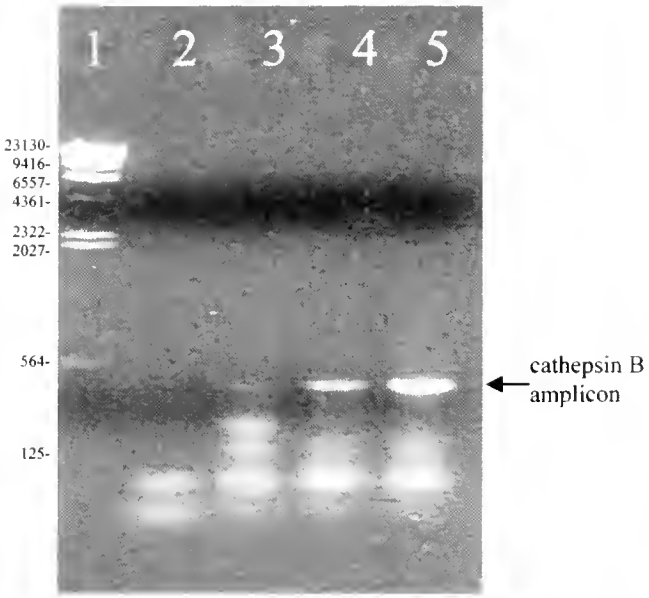

Figure 5. RT-PCR analysis of cathepsin B gene expression in *C. gigas*. Total RNA was reverse transcribed and submitted to two rounds of PCR as described previously. A total of 5 µl PCR products were analyzed on a 1.2% agarose gel. Lane 1 = λ*Hin*dIII markers; lane 2 = –ve control; lane 3 = 100 ng RNA from adult digestive gland; lane 4 = 100 ng RNA from larvae 2 days before settlement; lane 5 = 100 ng RNA from larvae 2 days post settlement.

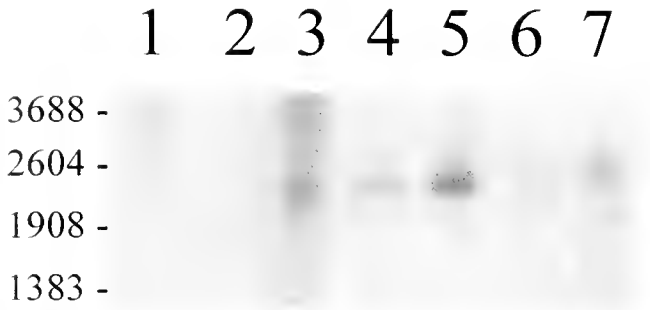

Figure 6. Northern blot analysis of *C. gigas* total RNA from adult and larval tissue. An [α-^{32}P]ATP-labelled 450-bp fragment of *C. gigas* cathepsin B DNA was hybridized with total RNA from adult and larval tissue. Lane 1 = 30 µg RNA from adult digestive gland; lane 2 = 30 µg RNA from adult adductor muscle; lane 3 = 30 µg RNA from adult gonads; lane 4 = 30 µg RNA from larvae 1 day post fertilization; lane 5 = 100 µg RNA from larvae 1 day post fertilization; lane 6 = 30 µg RNA from larvae 2 days before settlement; lane 7 = 30 µg RNA from larvae 2 days post settlement 2 µ l RNA markers (Promega) were run alongside RNA samples, the molecular weights were indicated.

cathepsin B transcript of approximately 2.4 kb in larval tissue and in adult gonad tissue. No expression was detectable in RNA extracted from adult digestive gland or adductor muscle.

DISCUSSION

To our knowledge, this is the first study to adopt molecular techniques to clone and partially sequence a gene encoding a the proteolytic enzyme cathepsin B in any shellfish. The amino acid sequence of cathepsin B in *Crassostrea gigas* showed 60, 59 and 58% identities to cathepsin B amino acid sequences in the human, cow and rat, respectively. Despite the obvious evolutionary distance between *C. gigas* and the three mammalian species, there is still a high degree of similarity between the oyster and mammalian cathepsin B sequences. It has been previously reported that bivalve cathepsins do share certain biochemical properties with mammalian cathepsins (Zeef & Dennison 1988). For example, the surf clam (*Spisula solidissima*) has been shown to possess a cathepsin with similar specificity and inhibition properties to mammalian cathepsin B (Chen & Zall 1986).

We detected cathepsin B gene expression in all developmental stages that we tested, reflecting the essential nature of proteolysis in repair, sanitation and metabolic regulation (Hawkins 1991, Ciechanover & Schwartz 1994). Northern blot analysis indicated that the level of cathepsin B expression was higher in larvae than in adult tissue; so much so that the level of cathepsin B expression was too low to be detected by northern blot analysis in adult digestive gland or adult adductor muscle tissue. This was consistent with our expectation of fast protein turnover during periods of rapid larval development (Fujii et al. 1991, Hawkins 1991). In adults, cathepsin B gene expression was only sufficient to be detected at the northern blot level in gonadal tissue. It is likely that this relatively high level of transcription occurred because the oysters had recently spawned, after which there is significant breakdown and reorganization of the remaining cells (Peek & Gabbott 1990).

In summary, we have developed a molecular probe to measure expression of the cathepsin B gene in *C. gigas*. We have detected expression of that cathepsin B gene throughout development, using RT-PCR. Findings indicate that the level of cathepsin B expression varied according to life stage, with higher levels of expression in larval tissue. Using this probe, our future work will relate expression to both the quantity (by western blotting) and activity (by biochemical assay) of cathepsin B, thus helping to resolve the mechanisms regulating cellular levels of this key proteolytic enzyme.

ABSTRACT Commercially marketed kits are now available for PCR reactions. This study was conducted to determine the suitability of one of these kits (PCR supermix kit from Life Technologies Inc) for use in environmental testing for rotavirus in commercially cultured oysters. We focused on developing a rapid, efficient and inhibitor-free oyster-processing procedure which could be used for sensitive viral genome amplification by reverse transcripts PCR (RT-PCR) in raw oysters using a commercial kit for genome amplification. Rotavirus SA11 strain was used to evaluate the efficiency of virus recovery. Oyster tissues were seeded with 3×10^7 ffu of rotavirus. Oyster-processing included elution in TPB (Tryptone phosphate broth)/glycine (pH 9.0), virus precipitation using polyethylene glycol, sonication, and RNA extraction. RNA extraction methods evaluated included CTAB/SDS followed by phenol/chloroform extraction (standard method), or the commercial reagent TRIZOL LS™. Both were equally effective for removal of PCR inhibitors. Detection limit of the method described in this study was 0.03 ffu rotavirus SA11 recovered from the oyster tissues. We conclude that the Supermix® commercial PCR kit can provide a more rapid and sensitive alternative for virus detection in oysters when compared to traditional PCR protocols. This is especially beneficial when large numbers of environmental samples require analysis.

KEY WORDS: oysters, RT-PCR, PCR supermix® kit, rotavirus

INTRODUCTION

Enteric virus transmission through consumption of fecally-contaminated shellfish is a significant public health concern (Richards 1985, Jaykus et al. 1994). Fecal coliforms have long been considered the best, if imperfect, indicators of fecal pollution. However, these indicators have come under increasing scrutiny as acceptable indicators of viral health hazard in commercial shellfish, and waters used for their cultivation (CDC, 1991). The primary arguments against use of fecal coliforms as indicators of fecal pollution are:

1. Shellfish and waters with acceptable levels of fecal coliforms may still be contaminated with enteric viruses.
2. Depuration methods for removal of bacterial pathogens from shellfish have not consistently removed viruses.
3. Depurated shellfish have been proven a source of outbreaks of viral-induced gastroenteritis (Sobsey et al. 1987, Caul et al. 1993).

In addition, Abad et al. (1997) demonstrated that pathogenic viruses could be detected in mussels from areas regarded as unpolluted, safe for swimming, and suitable for harvesting shellfish using standard bacterial indicators. In the absence of effective indicators, investigators have attempted the direct detection of viruses from shellfish and their cultivation waters. Shellfish are readily contaminated with viruses present in sewage contaminated waters due to the concentration effect of filter feeding (Larkin & Hunt 1982, Gerba 1988, Cromeans et al. 1997, Barardi et al. 2001). Since viruses do not replicate in shellfish tissues, the vector potential of shellfish is thought to be due to the stability of viruses in their tissues. The risk of acquiring a shellfish-borne viral disease is substantial as they are often eaten raw, including the intestinal tract (Heller et al. 1986, Wanke & Guerrant 1987, Speirs et al. 1987, Bouchriti & Goyal 1993, Kohn et al. 1995). In addition, cooking experiments performed with artificially contaminated mussels revealed that five minutes after the opening of the mussel valves, rotaviruses and hepatitis A virus could still be recovered in steamed shellfish. Under commercial depuration conditions, health-significant enteric viruses, such rotavirus and hepatitis A virus, could be recovered from bivalves after 96 hours of immersion in a continuous flow of ozonated marine water (Abad et al. 1997).

Rotaviruses represent 80% of recognized viral etiologies, and 140 million cases of diarrhea per year worldwide. Structurally, rotaviruses belong to the "naked" class of viruses. These are generally more environmentally resistant than enveloped viruses (Gerba et al. 1996). They are commonly found in wastewater and in addition can be concentrated by shellfish. Thus, the environment constitutes a significant reservoir for the virus (Bajolet & Chippaux-Hyppolite 1998). Examination of shellfish for viral contamination has generally relied on cell culture (Berg et al. 1984, Cromeans et al. 1997, Suñén & Sobsey 1999). However, wild-type enteric viruses do not readily grow in cell culture. They also generally require long periods of adaptation and specific antigen assays for virus detection, since no visible cytopathic effect is produced in vitro. Polymerase chain reaction (PCR) can be used to enzymatically amplify nucleic acid sequences present in low copy numbers in environment samples to detectable levels. The speed, specificity, low cost, and ease of use of PCR have led to its increasing use in environmental science (Metcalf et al. 1995, Abbaszadegan et al. 1999). Despite the sensitivity of PCR reactions, interfering substances in the environmental samples can severely limit the usefulness of this approach (Schwab et al. 1993, Atmar et al. 1993, Shieh et al. 1995).

The overall objective of this study was to evaluate and establish a new, molecular-based protocol to routinely monitor shellfish for infectious viruses, using rotavirus SA11 and the oyster *Crassostrea gigas* as a virus-shellfish model system. We evaluated a simple protocol for oyster extract preparation, and a cost-effective method for viral RNA isolation from these extracts. After cDNA

*Corresponding author. Tel.: +55-48-331-5207; fax: +55-48-331-9258; E-mail: ceb1crb@ceb.ufsc.br

synthesis, the strategy was to use a PCR kit together with specific primers capable of rapidly identifying the presence of infectious viral pathogens in environmental samples through genome amplification with the accuracy and speed required for routine shellfish monitoring by laboratories.

Rotaviruses were chosen as a model to develop this assay as they are responsible for severe gastroenteritis in humans and animals. They have been implicated in outbreaks of waterborne gastroenteritis in many countries (Ansari et al. 1991). After replicating in the gastrointestinal tract, they are excreted and may be dispersed in environmental waters (Kapikian & Chanock 1996, Hart & Cunliffe 1997). The stability of human rotaviruses in environmental waters, and their resistance to physico-chemical treatment processes in sewage treatment plants may facilitate their transmission (Hurst & Gerba 1980). In addition, their presence in drinking water, (Deetz et al. 1984, Strappe 1991) sea water, (Goyal & Gerba 1983) and shellfish (Lewis & Metcalf 1988, Hafliger et al. 1997) has been described.

MATERIALS AND METHODS

Virus and Cells

Simian rotavirus SA11 (group A, simian serotype G3) was propagated and assayed by indirect immunofluorescence in MA104 cells, a continuous line of fetal Rhesus monkey kidney. Cells were cultivated in Eagle's minimal medium (MEM) supplemented with 1X non-essential aminoacids, 15 mM Hepes buffer, 2 mM glutamine and 10% (v/v) fetal calf serum (Birch et al. 1983). Infected fluid was titrated by indirect immunofluorescence assay as described by Barardi et al. (1998) using 10 μg/ml of trypsin in the maintenance medium (as described above without Fetal Calf Serum).

Experimental Design for Viral Recovery Studies

Oyster Inoculation

Oysters (*Crassostrea gigas*) were obtained from a cultivated system oyster farm in Florianópolis City, Santa Catarina State, Brazil. Oyster shells were scrubbed with a stiff brush in running potable water (ca. 0.7 ppm free chlorine). Shell surfaces were then coated with a 70% ethanol solution and left to air dry for 30 minutes at room temperature in a biological safety cabinet. Shells were then opened at the hinge with an autoclaved oyster knife. Each oyster was seeded with 300 μl of rotavirus-infected tissue culture supernatant containing 3×10^7 focus forming units (ffu) using a micropipette tip inserted at three points of the visceral area as described previously (Cromeans et al. 1997, Barardi et al. 1999). After adsorption for 30 minutes at room temperature, the oyster extract was prepared (see later in text). Negative controls consisted of washed and disinfected shells from non-seeded oysters from the same source.

Oyster Extract Preparation

The following method for preparation of virus extracts from oysters was examined for effectiveness of viral recovery for the subsequent RT-PCR assay (Barardi et al. 1999 with minor modifications): 10–20g of oysters flesh were transferred to a sterile Schott® bottle containing 100 ml of pre-chilled (ice bucket) 10% (v/v) tryptose phosphate broth (TPB) (100% TPB contains 20g tryptose, 2.0g glucose, 5.0g NaCl and 2.5g Na_2HPO_4, pH 9.0) prepared in 0.05M glycine (pH adjusted to 9.0 using 2N NaOH). Tissues were then homogenized with a shaft blender (Ultra-Turrax T-25 Ika®) at 24,000 rpm for 30s. The resulting homogenate was placed in a 50 ml centrifuge tube, shaken at 250 rpm for 30 min. at 22°C, and centrifuged at 10,000 Xg for 30 min at 4°C. The pellet was discarded and supernatant pH adjusted to 7.5 using 2M HCl. Polyethylene glycol solution (PEG, MW = 8000) (50%, w/v) prepared in 10% TPB was added to a final concentration of 8% (w/v). The mixture was stirred for 2 h at 4°C, then centrifuged at 10,000 ×*g* for 20 min a 4°C. The supernatant was discarded and the pellet resuspended in 5.0 ml of 0.15 M Na_2HPO_4, pH 9.0. The resuspended pellet was then sonicated at high power twice for 30s and transferred to a fresh centrifuge plastic tube and the pH readjusted to 7.4 using 2M HCl. This preparation was designated oyster extract B (Fig. 1).

To study the effectiveness of this virus extraction method using both PCR and RT-PCR, unseeded oysters were extracted using the same procedure. These oyster extracts were then seeded with the same amount of virus used for preparation of spiked-whole-oyster extracts. Seeded extracts were designated as positive controls-A (Fig. 1).

Viral RNA Extraction from Oysters Extracts

Two techniques of viral RNA extraction were compared for their effectiveness in detecting Rotavirus genome from oyster extracts by RT-PCR. **Technique I** (Barardi et al. 1999): An aliquot (0.5 ml) of each oyster extract: A (positive control) and B (experimental extract) (equivalent to 2.5×10^7 ffu) were used for viral RNA isolation. An equal volume of trichlorotrifluoroethane (Aldrich) was added to remove lipids from each aqueous oyster extract, and the suspensions centrifuged at 6,000 rpm in a microcentrifuge (Eppendorf®) for five minutes at room temperature. The aqueous phase was transferred to another sterile Eppendorf® tube. Tris-HCl (pH 7.5), EDTA, SDS and proteinase K were added at final concentrations of 10 mM, 5 mM, 0.5% (w/v) and 400 μg/ml, respectively. Samples were then incubated at 37°C for 30 min. Cetyltri-

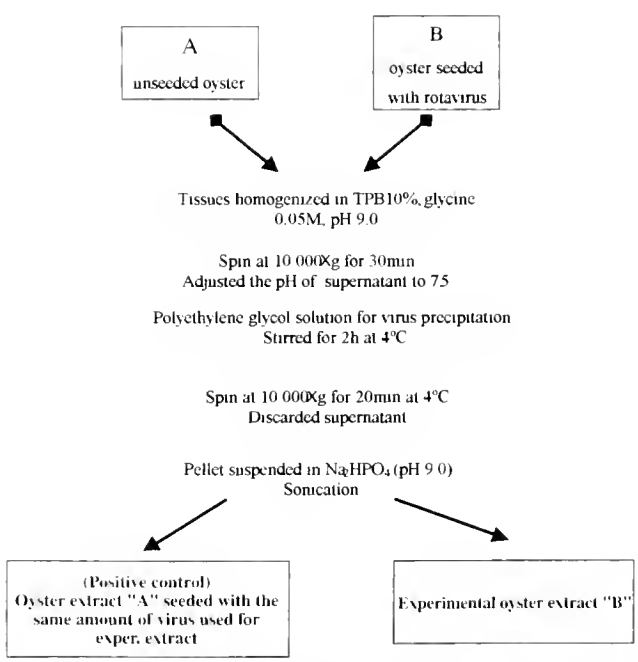

Figure 1. Outline of techniques used to prepare oysters extracts A, and B prior to detection using RT-PCR.

methylammonium bromide (CTAB) and NaCl were added to final concentrations of 1.3% (w/v) and 0.52 M, respectively, and samples incubated at 56°C for 30 min. Samples were subsequently extracted twice with an equal volume of phenol-chloroform-isoamyl alcohol (25:24:1). The aqueous phase was transferred to another microfuge tube and an equal volume of chloroform added. The aqueous phase was then precipitated in 3 vol of chilled 100% ethanol at −20°C. Resulting pellets were washed with chilled 70% (v/v) ethanol, suspended in 50 µl of Milli-Q water, and stored at −20°C for RT-PCR assays. **Technique II**: An aliquot (0.5 ml) of oyster extracts (A and B) was used for viral RNA isolation. According to manufacturer specifications, each sample was added to 1.5 ml of TRIZOL LS™ reagent and residual cells in the sample lysed by passing the suspension several times through a blue tip form P-1000 micropipette. Samples were incubated for five minutes at room temperature, 0.4 ml of chloroform added, and the sealed tube shaken vigorously by hand for 15 seconds. Samples were then incubated at room temperature for 10 minutes followed by centrifugation at 12,000 ×*g* for 15 minutes at 28°C. The aqueous phase was transferred to a fresh tube and 0.5 ml of isopropyl alcohol added, followed by incubation at room temperature for 10 minutes and centrifugation (12,000 ×*g*, 10 min, 4°C). The supernatant was removed and pellet washed once with 1 ml, 75% ethanol. At the conclusion of the procedure the RNA pellet was air dried, suspended in 50 µl of Milli-Q water, and stored at −80°C for RT assays.

RT-PCR Assays

The level of rotavirus detection by RT-PCR was determined for the extracts A (positive control) and B (experimental extract) using 2-fold serial dilutions of viral RNA ranging from 1:5 to 1: 5,000,00 and corresponding, respectively, to 2×10^4 to 0.015 ffu. **Primers:** the oligonucleotide primers BEG9 (5′-GGC TTT AAA AGA GAG AAT TTC CGT CTG G-3′) and END9 (5′-GGT CAC ATC ATA CAA TTC TAA TCT AAG-3′) (Gouvea et al. 1990), were used for reverse transcription and first PCR. These primers produce full-length copies of gene 9 (1062 base pairs) from any group A rotavirus strain. The primers ET3 (5′-CGT TTG AAG AAG TTG CAA CAG-3′) and END9 were used for the serotype-specific semi-nested PCR (second amplification-374 base pairs) (Gouvea et al. 1990), as the SA11 simian rotavirus, which belongs to serotype G3, has been used as a model for group A rotaviruses in this study.

Two RT-PCR protocols were compared for their sensitivity to detection of the lowest quantity of viral RNA. **Protocol 1:** (Barardi et al. 1999 with minor modifications). 5.0 µl aliquots of diluted RNA isolated either by technique I or II (in separate reactions) and 200 pmol BEG9 and END9 primers were heated at 99°C for 5 min, followed by chilling on ice for 1 min. The denatured RNA was added to the reaction mix consisting of 20 mM Tris-Cl, pH 8.4, 50 mM KCl, 0.4 mM each dATP, dCTP, dTTP and dGTP, 1.5 mM $MgCl_2$, 10 mM DTT and 40 units M-MLV reverse transcriptase (GibcoBRL). Reverse transcription of viral genomic RNA was carried out at 37°C for 90 min After this step, 5 units *Taq* DNA polymerase were added, and tubes overlayed with mineral oil. PCR amplification was carried-out for 25 cycles of 94°C for 1 min, 55°C for 2 min and 72°C for 3 min, and a final 10 min incubation at 72°C. For semi-nested PCR, 2.0 µl of the first PCR product was added to the reaction mix of 50 µl containing 20 mM Tris-HCl, pH 8.4, 50 mM KCl, 0.2 mM each dATP, dCTP, dTTP and dGTP, 3.0 mM $MgCl_2$, 100 pmol ET3 and END9 primers, and 5 units *Taq* DNA polymerase. Tubes were then overlayed with mineral oil and the same PCR program used. **Protocol 2:** The PCR Supermix® kit (GibcoBRL) was used in this protocol. The manufacturer's protocol was followed, except for the concentration of $MgCl_2$ (see later in text). Five µl aliquots of diluted RNA isolated either by technique I or II (in separate reactions) were heated at 99°C for 5 min, then chilled on ice for 1 min. The denatured RNA was added to the reaction mix consisting of 50mM Tris-HCl, pH 8.3, 75 mM KCl, 3.0 mM $MgCl_2$, 0.5 mM each dATP, dCTP, dTTP and dGTP, 5 mM DTT, 100 pmol BEG9 and END9 and 40 units M-MLV reverse transcriptase. Reverse transcription of viral genomic RNA was carried out at 37°C for 90 min. After this step, 2.0 µl of reverse transcriptase product and 100 pmol BEG9 and END9 were added to 45 µl of the commercial reaction mix containing 22 mM Tris-HCl, pH 8.4, 55 mM KCl, 1.65 mM $MgCl_2$, 0.22 mM each dNTP and 22 units/ml *Taq* DNA polymerase. Additional $MgCl_2$ was added to the reaction mix to achieve a final concentration of 3.0 mM. Tubes were overlayed with mineral oil and heated at 80°C

Lanes 1 and 9: molecular weight marker; lanes 2 to 8: serial dilutions of viral RNA corresponding from 1.6×10^5 to 625 ffu respectively. (C) B extract (exp. extract). Lanes 1 and 15, molecular weight marker, lanes 2 to 13: serial dilutions of viral RNA corresponding from 1×10^5 to 0.07 ffu, lane 14: negative control. (D) A extract (positive control). Lanes 1 and 17: molecular weight marker; lanes 2 to 15: serial dilutions of viral RNA corresponding from 1×10^5 to 0.015 ffu, lane 16: negative control.

TABLE 1.

Sensitivity of RT-PCR for rotavirus detection using both PCR protocols with the different oyster extracts.

	Limit of Viral Detection (ffu)	
Oyster Extracts	PCR Traditional	PCR Supermix Kit
A (positive control)	312	0.03
B (experimental test)	625	0.15

for 1 min. The same PCR program described above was then used. PCR products were analyzed by electrophoresis in 1.5% (w/v) agarose, or 10% (w/v) polyacrylamide gels. Both were stained with ethidium bromide at 10 μg/ml, and visualized under UV light. Either nucleic acids isolated from non-seeded oyster extracts or just distilled water were used as negative controls for the RT-PCR reactions.

RESULTS

Sensitivity of Rotavirus Detection Using RT-PCR Assays

The sensitivity of two RT-PCR assays for virus detection was evaluated using total RNA isolated from oyster extracts A (positive control) and B (experimental extract). The RNA from both extracts were isolated according to Techniques I and II. Both techniques were equally effective for RNA isolation for the RT-PCR reactions (not shown). The minimum amount of virus (ffu) that could be detected in the second PCR (semi-nested) using the traditional PCR protocol (protocol 1) was 312 ffu for extract A (positive control) and 625 ffu for extract B (experimental extract). PCR Supermix® kit (protocol 2) was also used for oyster extracts A and B In this case, the minimal amount of virus (ffu) that could be detected in the second PCR (semi-nested) was 0.03 ffu for extract A (positive control) and 0.15 ffu for extract B(exp. extract). These results can be seen in Figure 2. Table 1 summarizes the sensitivity of RT-PCR using both PCR protocols.

DISCUSSION

Nested or semi-nested RT-PCR systems are among the most sensitive molecular biological detection methods available today, with the ability for detection of as little as a single copy of a viral genome (Hafliger et al. 1997). This paper describes the evaluation and establishment of a rapid and reliable protocol for virus detection in artificially-inoculated oysters using a commercial PCR kit for genome amplification. Rotavirus SA11 and the oyster *Crassostrea gigas* were used as a model system to evaluate the efficacy of two viral RNA isolation techniques, and the sensitivity of subsequent virus detection using two different RT-PCR methods. Two procedures were compared for purification of viral RNA from artificially infected oyster extracts. There was no relevant difference in rotavirus detection by RT-PCR between the two methods. TRIZOL LS™ reagent, a mono-phasic solution of phenol and guanidine isothiocyanate, followed by chloroform proved to be effective for viral RNA purification. So, only results obtained with the less expensive method for nucleic acid extraction (phenol-chlorophorm) were presented, using two different RT-PCR protocols. Comparison of results obtained by RT-PCR, followed by semi-nested PCR detection, had confirmed that when the PCR Supermix® (a ready-to-use mixture of recombinant *Taq* DNA polymerase, salts, magnesium, and deoxyribonucleotide triphosphates) is used, the limit of virus detection was 0.03 ffu for the positive control (A), and 0.15 ffu for the experimental extract (B). In both cases, this was 4,000 to 10,000 times more sensitive when compared with the virus detection limit using the traditional PCR protocol where all reagents were added separately.

This study demonstrates improvements and simplification of a highly sensitive and simple method to prepare oyster tissue extracts, and application of a specific and sensitive RT-PCR based system for the detection of rotavirus. We anticipate that the methods described here will be further improved and optimized in a single multiplex PCR reaction for detection of a greater variety of human enteric viruses commonly found contaminating shellfish and aquatic environments.

POPULATION STRUCTURE AND DEMOGRAPHY OF THE PUELCHE OYSTER (*OSTREA PUELCHANA*, D'ORBIGNY, 1841) GROUNDS IN NORTHERN PATAGONIA, ARGENTINA

MARCELA S. PASCUAL,[1]* EDUARDO A. ZAMPATTI,[1] AND OSCAR O. IRIBARNE[2]**

[1]*Instituto de Biología, Marina y Pesquera, "Alte. Storni", CC 104, (8520) San Antonio Oeste, Río Negro, Argentina;* [2]*Facultad de Ciencias Exactas y Naturales, Universidad Nacional de Mar del Plata, CC 573, (7600) Mar del Plata, Argentina*

ABSTRACT The three main grounds of the flat oyster (*Ostrea puelchana*, D'Orb.) are located at the northwestern portion of the San Matías Gulf, at Northern Patagonia, Argentina. The population structure and demography of the grounds at Banco Reparo, Las Grutas and Bajo Oliveira were studied through several diving and dredge surveys performed between 1985 and 1991. The complete population of the grounds located at Banco Reparo and Bajo Oliveira, and the population of the central part of Las Grutas ground, were assessed, measuring oyster density and spatial distribution, size structure, proportion of clustered and free oysters, proportion of oysters carrying epibiotic males, and oyster's life habit. The puelche oyster is distributed almost continuously along the northern coastal area of the San Matías Gulf, at depths ranging from two to 20 minutes. The grounds are likely to be interconnected by larval dispersion. The three studied grounds differed in their demographic characteristics, and it was difficult to compare biomass between the grounds due to different methods of assessment. However, the results enabled us to conclude that high oyster density areas were always limited on any of the grounds, with maximal densities only on relatively small patches. Patches of recruits were never found in the surveys, suggesting that a clear spatial segregation of settlement does not occur in this species. Oyster size structure at Banco Reparo and Las Grutas was similar, while individuals at the Bajo Oliveira population were very large, with mean population size 20 mm larger than on the other two grounds. Size classes below 45 mm were always poorly represented or absent on the three grounds. The portion of the population comprising of individuals <30mm was represented by the epibiotic males who represented a "hidden" mode. The three populations differ in their dynamics, mainly in the turnover rates of individuals. At Bajo Oliveira the medium size individuals are absent (there is a hiatus between the two modes) and the mean size of adult oysters is the largest (89 mm). In contrast, at Las Grutas, the intermediate sizes between the two modes are present (there is no hiatus between the two modes) and the mean size of adults is the smallest (66 mm). Banco Reparo occupies an intermediate position. Based on this information we suggest that turnover rate is then maximal at Las Grutas, intermediate at Banco Reparo, and minimal at Bajo Oliveira. The puelche oyster grounds at the San Matías Gulf offered the rare opportunity of studying the structure of one of the few natural and untouched flat oyster populations in the world. Work helped support the closure of the fishery as a policy mainly based on the vulnerability of the stocks.

KEY WORDS: oysters, *Ostrea puelchana*, Patagonia, natural grounds, demography, density distribution

INTRODUCTION

Ostrea puelchana (d'Orbigny 1841), commonly named "puelche" or "Patagonian", is a flat oyster belonging to the Family Ostreidae (Subfamily Ostreinae) (Stenzel 1971). This species is distributed from Rio Grande do Sul (30°S, 50 W, Brasil) to Bahía Camarones, Northern Patagonia (44°S, 66°W, Castellanos 1957) (Fig. 1). Dense aggregations ("grounds") have been reported only at the southern limit of their distribution (Valette 1929, Castellanos 1957, Fernández Castro 1987, Pascual & Bocca 1988, Pascual 1993). However, there has been recent evidence of the presence of the species in deep waters (30–35 m depth) off the State of Santa Catarina, Brasil (Carlos Polis & Jaime Ferreira, pers. comm.). The distributional area of *O. puelchana* should then be extended northwards. Isolated individuals regularly appear along the northern Argentinean coast as by-catch in the mussel dredge fishery off Buenos Aires shores (M. Lasta, pers. comm.), and at intertidal sites of the same area. The occasional appearance of flat oysters has been reported for several localities along the coast of Buenos Aires Province (35–40 S; 57–62 W).

The presence of this species in Argentina was first reported by D'Orbigny (1841) who, as indicated by Castellanos (1957) misidentified this species as *Ostrea spreta*, a non commercial flat oyster that cohabits with *O. puelchana* at shallow coastal waters of the San Matías Gulf (40°40'S; 63°30'W) (Fig. 1). *O. spreta* is a small oyster, pink to purple colored, that attains a maximal size of 50 mm and forms beds inside San Antonio Bay (Fig. 1), in environments of strong tidal currents. Extreme types of both species may be easily recognized but a wide gradient of morphological characteristics makes the identification of young individuals difficult.

Ostrea puelchana has solid shells, lamellated and subnacreous, circular or subsquare. The upper or right shell is flat and lamellated. The lower or left shell is bigger, lamellated and convex (Castellanos 1957). The individuals have a diverse coloration, the juveniles are homogeneously cinnamon colored but frequently showing shells with longitudinal purple estriae. The adult specimens loose their cinnamon color and show yellow greenish or gray shells.

The puelche oyster lives isolated or in clusters. A cluster is formed when the larvae settle and grow on the shells of a "founder" oyster. The maximal size registered in this species is 140 mm of total height (TH: largest diameter from the umbo to the opposite margin). This size is rare, however, with size generally up to 120 mm in deep populations. Age is difficult to assess in this species; attempts at age revelation from readings on shell cuts have been unsuccessful. Nevertheless, external characters such as the thickness of the ligament and the rate of infection by perforating sponges, *Cliona celata* or the Mitylid *Litophaga patagonica*, suggest that it is a long-lived species.

The structure of some of the puelche oyster populations of the San Matías Gulf has been studied for the last 20 years. Most of this information is contained in unpublished technical reports (Vacas 1978, Vacas 1979), a thesis (Pascual 1993), and some has been published (Morriconi & Calvo 1989). A great amount of research effort was dedicated to the sexuality of this species (Calvo & Morriconi 1978, Morriconi & Calvo 1979, Fernández Castro 1987, Fernández Castro & Lucas 1987, Pascual et al. 1989, Pascual &

*E-mail: ostra@canaldig.com.ar **E-mail: ostriba@mdp.edu.ar

Zampatti 1995, Pascual 2000). *O. puelchana*, while fitting the general reproductive pattern of brooding Ostreas, shows an alternative breeding system that makes it unique among Ostreids. In natural grounds, oysters change their sex to the female phase when they reach a shell size of 50–55 mm. At this point, the oyster acquires the ability of "carrying" small conspecific individuals settled on an expansion ("platform") of the anterior margin of the concave shell (Calvo & Morriconi 1978). These epibiotic oysters are always males during the reproductive season and their gonads mature synchronously with the gonads of its female "carrier" (Calvo & Morriconi 1978). The epibiotic males have their growth rate severely reduced by the influence of the female carrier (Pascual et al. 1989). This "dwarf" condition assures the persistence of each couple (carrier oyster + epibiotic male) for long periods of the carrier's lifetime.

The populations of the puelche oyster of the San Matías Gulf have been protected by a legal fishing closure established in 1971. This rare legal interdiction has been based for many years on the assumption of the vulnerability of the stocks. However, it was not before 1985 that a thorough sampling of the oyster grounds was initiated through the San Matías Gulf Oyster Project. This project was intended to gain knowledge on the demographic structure and spatial extent of the puelche oyster stocks, and on the reproductive ecology of the species. Simultaneously, an Oyster Culture Project has been developed.

The present paper presents information obtained from extensive surveys performed between 1985 and 1991 on the population structure and dimensions of the three main oyster grounds of the NW San Matías Gulf: Banco Reparo (BR), Las Grutas (LG), and Bajo Oliveira (BO) (Fig. 1).

MATERIALS AND METHODS

Study Site and Background Information

The Banco Reparo oyster ground is located in the NW San Matías Gulf (40°40′S; 63°30′W) (Fig. 1). The bottom is sandy, partially covered by pebbles and mollusk shells. Currents are strong (26–52 cm s^{-1}) and depth ranges from 2–3 m at low tide. Tidal range is 7.62 m in spring, and 5 m during mean tides (Servicio de Hidrografía Naval, 1969). Seawater temperature ranges from 7°C (August) to 23.5°C (January); and salinity ranges from 34–36‰ (Fernández 1989). The highest values of *chlorophyll a* are reached in March (23 mg l^{-1}), while the maximal values of phosphates and nitrites/nitrates are reported in spring (0.13 μg l^{-1}, and 9.25 μg l^{-1} respectively) (Fernández 1989). Dissolved oxygen fluctuates seasonally reaching its maximal value in August (7.69 mg l^{-1}) (Fernández 1989).

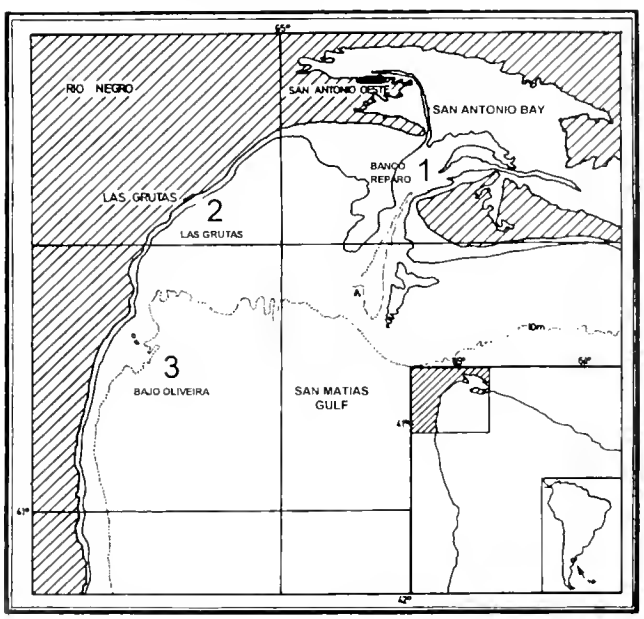

Figure 1. Location of the three main oyster grounds along the San Matías Gulf coast, Northern Patagonia (1 = Banco Reparo; 2 = Las Grutas, and 3 = Bajo Oliveira).

The Las Grutas oyster ground is located on open waters on the NW coast of the gulf, 15 km south from Banco Reparo (40°48′S; 65°05′W, Fig. 1 and Fig. 3). The bottom is composed of coarse sand and shell, occasionally interrupted by limestone platforms crossed by channels filled with sand. Tidal currents are weaker than in Banco Reparo (20–30 cm s^{-1}) and depth ranges from 2.5 to 6 m at low tide. Oysters live on sandy flats, on limestone platforms, and among dense stands of the macroalgae *Codium* sp. Water temperature ranges from 8°C (August) to 21°C (January), and salinity between 34 and 35‰ (Fernández 1989). The highest values of *chlorophyll a* were reported for March (42 mg l^{-1}, in 1987). Phosphates peak in April (10.5 μg l^{-1}), and nitrates/nitrites peak in March (13.5 μg l^{-1}). Dissolved oxygen shows a marked seasonality, reaching its winter peak on August (6.8 ml l^{-1}) (Fernández 1989).

The Bajo Oliveira oyster ground is located south from Las Grutas ground, also in the NW of the gulf (40°50′S; Figs. 1 and 3). The bottom is predominantly sandy and flat, covered by pebbles, small shell pieces and mollusk shells. Depth ranges from 4–22 m at low tide. Available oceanographic information is scarce and was gathered during a two survey conducted during 1971 and 1991 over the entire gulf, both performed in autumn, during which only one or two stations were located at Bajo Oliveira (Carreto & Verona 1971, Estéves et al. 1991). During those surveys salinity ranged from 33.9–34.9‰, *chlorophyll a* from 0.7–1.8 mg l^{-1}, nitrates were 0.78 μg l^{-1}, phosphates were 1.33 μg l^{-1} and water temperature was 17°C.

Sampling Design

At Banco Reparo, an area 1853 m long and 400 m wide, corresponding to the surface actually occupied by oysters, was positioned, on the basis of land references, and marked by buoys. A rectangular grid, comprising of 18, 2-m wide transects, each separated by a 100 m distance, was designed. Once each transect was positioned and marked, all the oysters found in each linear segment (10 × 1 m) at one side of the first sub-transect were collected by divers. The procedure was then repeated in the opposite direction. Thus, 20 sampling units were obtained on each sub-transect, and 80, as a maximum, over the entire transect. The eastern limit of each transect was determined by the absence of oysters along a distance of 100 m. The described procedure was performed 18 times and took 10 working days, from 23 October to 12 November 1985. The number of free oysters and clustered oysters was registered in each sample. All the oysters visible to the naked eye and one out of ten samples were collected and sized (total height in mm). Density data (oysters 10 m^{-2}) were used to produce a map of the population density distribution at the ground, this was used to estimate the area with different oyster densities. The area of the sectors included between isopleths was estimated by graphic computer software.

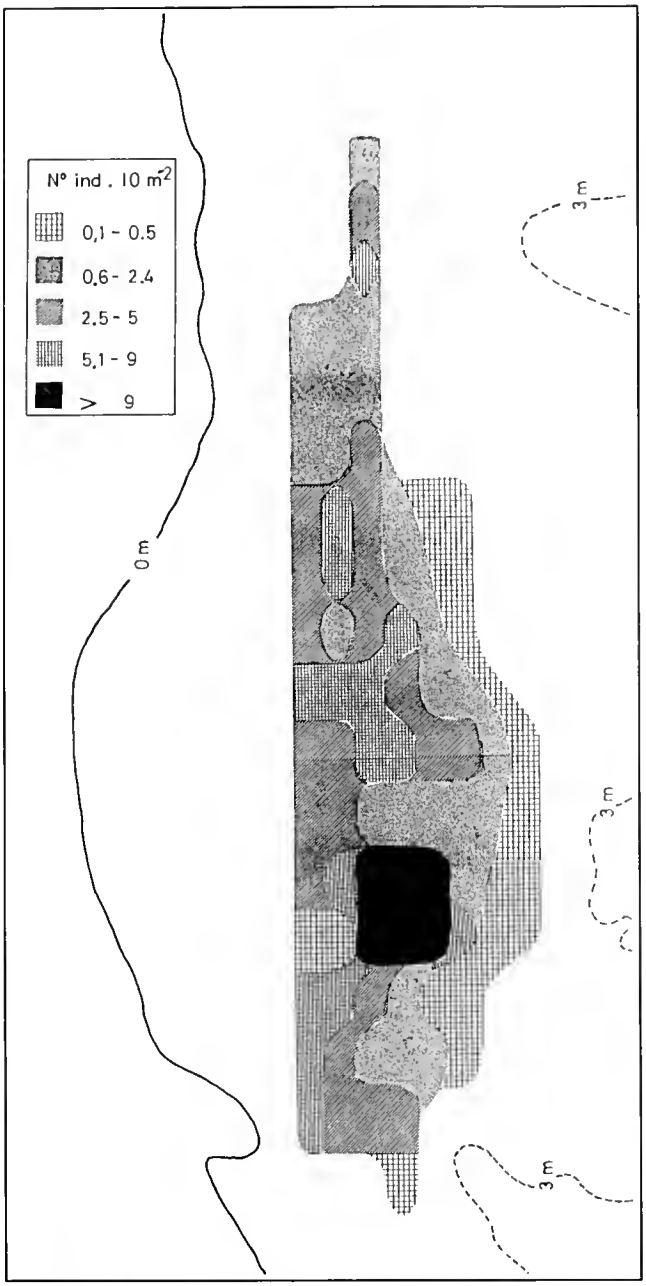

Figure 2. Distribution and abundance of oysters in Banco Reparo. Maximal densities are concentrated in the black stratum. Densities are number of oysters 10 m^{-2}.

Complementarily, sampling was performed to assess the predominant life position of individuals of different size ranges. Two transects, located in the center of the ground, were selected, and the divers registered, for each individual present along the two transects, its size and life position (oysters lying on its flat or on its concave shell). Oysters were allocated into three size groups: small (<3 cm); medium (3–7 cm) and large (>7 cm).

Sampling of oyster population structure at Banco Reparo was repeated October 1986 and November 1987 in the areas identified as high oyster density spots during the 1985 survey. A sample of all the oysters present in a 100 m transect was collected. Oysters from the samples were measured (total height: TH). The number and size of epibiotic (dwarf) oysters per carrier oyster were registered.

At Las Grutas only the central part of the ground, which was determined by previous sampling to have the highest density (marked by a star in Fig. 3), was prospected to describe the population structure. A station was fixed by a marking buoy and acted as a starting point from which seven radially spreading transects were laid out. Five to seven sampling units (1 m^2) were collected along each transect, at 15–20 m intervals. All the oysters within the frame were collected. The survey was completed between 16 to 28 November 1987.

The sampled oysters were separated as free and clustered oysters; they were measured (total height in mm) and counted. The epibiotic oysters fixed on the platform of carrier oysters (previously sacrificed) were also counted and measured.

Following the same procedure as in Banco Reparo, life position of oysters was also evaluated by diver collection of all oysters along a 200 m transect. Oysters lying on their flat shell or concave shell were collected in separate bags.

The Bajo Oliveira oyster ground, due to its great extent, had to be surveyed with a fishing research vessel equipped with a commercial dredge (mouth width: 2.5 m). Two surveys were conducted in June 1987 and May 1988. The first was the more detailed

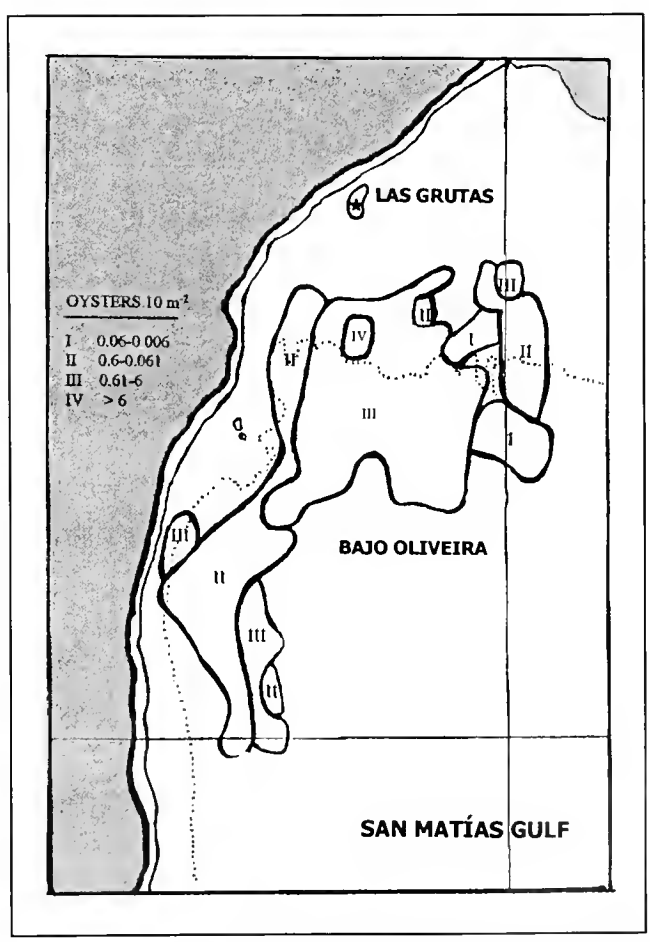

Figure 3. Oyster grounds at Las Grutas (the star indicates the central area of the ground where the survey was performed), and Bajo Oliveira with a map showing distribution and abundance of oysters estimated during the dredge survey (1987). Densities are number of oysters 10 m^{-2}.

one directed towards the assessment of the area covered by the oyster stock, the abundance distribution and the population structure; the second rendered additional information regarding population demography. The prospected area during 1987 had 122 km^2, with depths ranging from 4–22 m (Fig. 3). The survey was performed on a rectangular grid design, with legs parallel to the shore, each one divided in quadrats (1′ latitude by 1′ longitude). Stations were placed on the grid at regular intervals (one per quadrat) over each leg. The placement of sampling stations was made using radar and land references, and was corrected, when technically possible, by satellite readings. Each fishing tow lasted 10 minutes and swept an area of 2,700 m^2. Sixty stations were performed in four working days, recording initial and final depth, tow duration, and total unsorted catch weight. The catch from each haul was entirely stocked in 40 kg plastic bags. Three bags per haul (or the entire catch if not enough) were randomly sampled (or the entire capture in the case of poor hauls). The number of oysters, total weight of the oyster catch, and the weight of the rest of the components (inorganic and organic), were registered for each sampled bag. A sub-sample of each bag was used to size the oysters (TH in mm).

Over a total of six randomly chosen bags, separated on board, a detailed sampling was performed: oysters were sacrificed and "carriage" was assessed (number and size of epibiotic males on the platform of each oyster). Size (TH in mm) was recorded for each individual. Catch per haul data, obtained by multiplying the mean oyster catch in the sample by the total catch of the haul, were corrected by a gear efficiency factor of 15% (Iribarne et al. 1991). Catch and swept area per haul data were used to construct a map of density distribution on the ground. The area comprised between isopleths was estimated by computer.

Nine fishing hauls were performed at the N area of the ground during 1988 following the same procedure used in 1987. A sample consisting in one bag of clean catch (only oysters) was separated from the total catch of each haul. The oysters were sized and the epibiotic males on the platform of carrier oysters were counted and measured. The number of isolated and clustered oysters was reported for the entire catch of each haul.

The percentages of clustering and carriage between grounds were statistically compared by a Test of equality of percentages (Sokal & Rohlf 1969).

RESULTS

Spatial Distribution and Density

The Banco Reparo oyster ground occupies an area of 381,425 m^2 at depths ranging from 0.5–3 m at low tide. The ground lies in NE–SW direction, following the low tide mark, and parallel with the predominant tidal current (Fig. 2). Maximal density, 32 oysters 10 m^{-2}, was observed in a small area (0.24 km^2) located towards the SW side of the ground (Fig. 2, Table 1). It was not possible to identify a defined spatial pattern. Patches of variable density alternate, on the western side of the ground, over an area of shallow waters. The eastern side of the ground, on deeper waters, is a continuous fringe of low density. This limit is neatly marked and is defined by the presence of dense populations of Ophiuroids (Fig. 2).

At Las Grutas, oysters live on flat sandy areas as well as on limestone platforms and *Codium* prairies. However, the greatest concentrations were found on channels and depressions. The prospected area occupied a surface of, approximately, 2 km^2. Maximal density on the study area was 22 oysters per m^2. Mean estimated density for the complete prospected area was 8 oysters per m^2 (s = 5.3; N = 41).

IV	>6	3.25	7.06	–

The oyster ground of Bajo Oliveira occupies an area of 88 km^2, forming a ground elongated from north to south within the isobats of 10 and 20 m (Fig. 3). The northern portion of the ground extends out from the 10 m isopleth, extending onshore to a depth of 4 m (Fig. 3). The higher density area (Fig. 3; Table 1) (3.25 km^2) was located in the NW portion of the ground. The mid density areas occupy a central fringe and represent a 52.60% of the total area. The western and eastern sides of the ground are defined by low-density patches (Fig. 3). The maximal oyster density reported at this ground was eight individuals per m^2. The population is concentrated in a narrow depth range (5–13 m). Fishing hauls were also concentrated in this depth range and mainly in the 10 m isobat (46.6%).

Population Structure

The population of Banco Reparo is homogeneous, lacking spatial segregation of adults and juveniles. Free oysters (non clustered) had a mean size of 68.69 mm (s = 17.34; N = 1327) (Fig. 4). All samples had a very low number of individuals smaller than 40 mm (<5%). The percentage of oysters forming clusters in the 1985 samples ranged from 0–34%. Over the total stock of oysters examined in 1985, 1986 and 1987, the percentage of clustering was 19% (N = 1574); 88% of the clusters composed of 2 oysters, 9% by 3 oysters, and 3% by 4 oysters (N = 114). No clusters comprising of more than four oysters were reported at this ground. Mean size of free oysters (χ = 77.93 mm; s = 13.3; N = 122) was only slightly higher than the mean size of clustered oysters (χ = 71.13 mm; s = 16.87; N = 122) (Fig. 4). The 1986 and 1987 samples enabled the completion of the demographic study of the ground including the component corresponding to the epibiotic oysters settled on the platform of carrier oysters. The size frequency distributions were clearly bimodal (Fig. 4). In 1986, the first mode (epibiotic males) was 10.69 mm (s = 7.06; N = 111), and the second (free oysters), was 70.62 mm (s = 15.09; N = 209). In 1987, the modes were 12.69 mm (s = 6.82; N = 152), and 77.56 mm (s = 12.15; N = 388).

The percentage of "carriage" (oysters carrying dwarf males), in oysters bigger than 50 mm, estimated from samples of the 1986 and 1987 surveys (N = 946), was 32%. The carrier oysters of

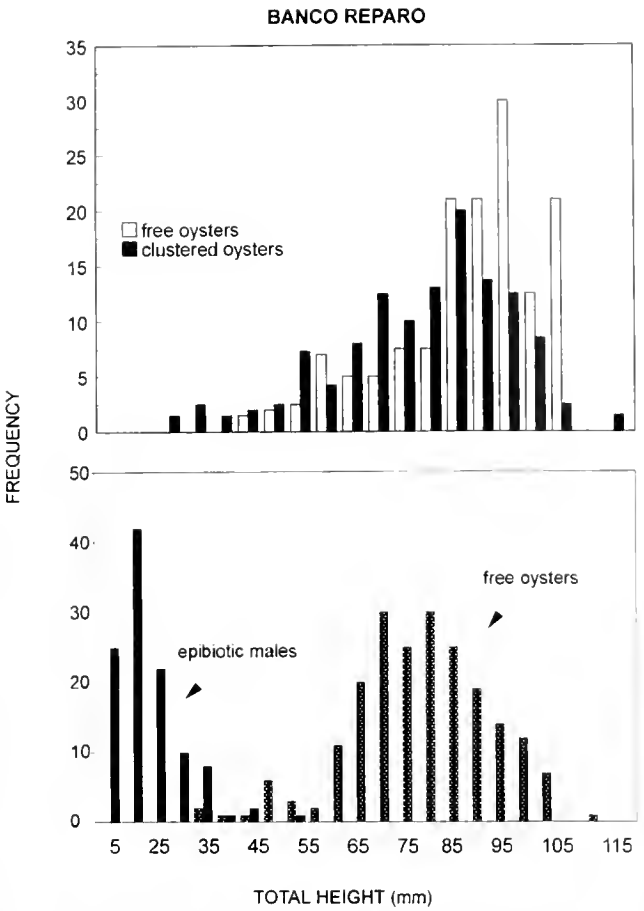

Figure 4. Banco Reparo. Size frequency distribution (total height in mm) of free and clustered oysters (above), and size frequency distribution of the complete population composed of free and epibiotic (dwarf males) oysters (below).

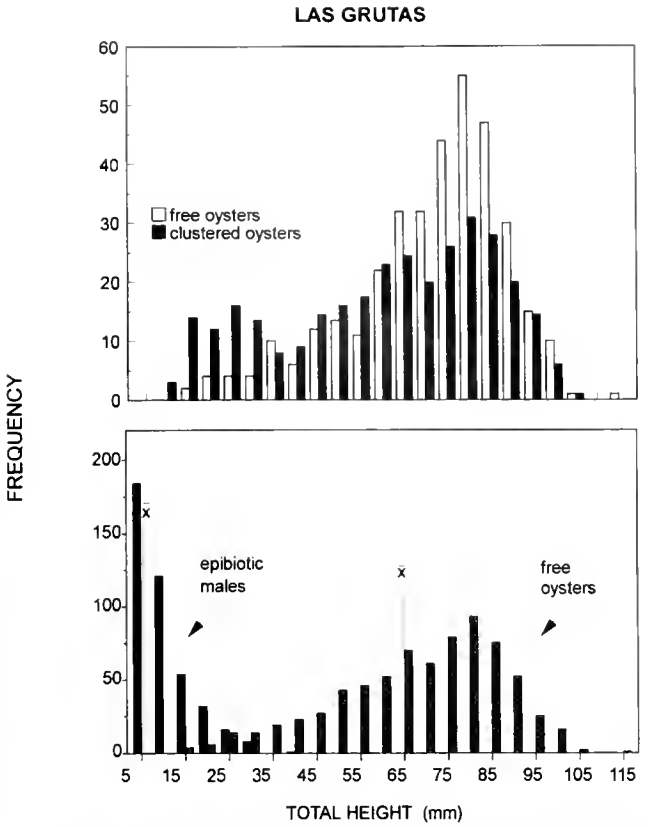

Figure 5. Las Grutas. Size frequency distribution (total height in mm) of free and clustered oysters (above), and size frequency distribution of the complete population composed of free and epibiotic (dwarf males) oysters (below).

Banco Reparo held a maximum of seven epibiotic males on the platform per oyster; 61% of the oysters carried one epibiotic male (mean = 1.69; s = 1.12; Table 2).

The total population of oysters at Las Grutas had a mean size of 66.67 mm (s = 18.67; N = 722). Free (non clustered) oysters had a mean size (χ = 69.05 mm; s = 18.18; N = 332) 10 mm higher than the group composed by clustered oysters (χ = 59.33 mm; s = 23.99; N = 317) (Fig. 5). The whole oyster population (including epibiotic males) presented a clear bimodal structure. The first mode, representing epibiotic males fixed on carrier oysters, was 8.2 mm (s = 6.3; N = 420), the second, representing the rest of the population, was 66 mm (s = 18.6; N = 722) (Fig. 5).

The clusters were composed of a maximum of 11 oysters of different sizes, those composed of only two oysters represented 47% of the total (mean = 3.26; s = 1.63). The proportion of clustered oysters was high in this ground: 44% of the sampled oysters (N = 627) had this life habit. The total estimated carriage (number of oysters >50 mm carrying epibiotic males) in the ground was 34% (N = 490). A maximum of six epibiotic males per carrier was registered, but 68% of the carriers (N = 259) were oysters carrying only one epibiotic male (Table 2).

The population of Bajo Oliveira is composed of large individuals. The mean size of oysters per haul in 1987 ranged from 77.6–94.2 mm (Fig. 6). Free oysters (isolated or clustered) presented a

Banco Reparo (BR), Las Grutas (LG), and Bajo Oliveira (BO). Percentages (arcsin transformed) were compared between grounds by a test of equality of percentages (P = 0.001) (Sokal & Rohlf 1969).

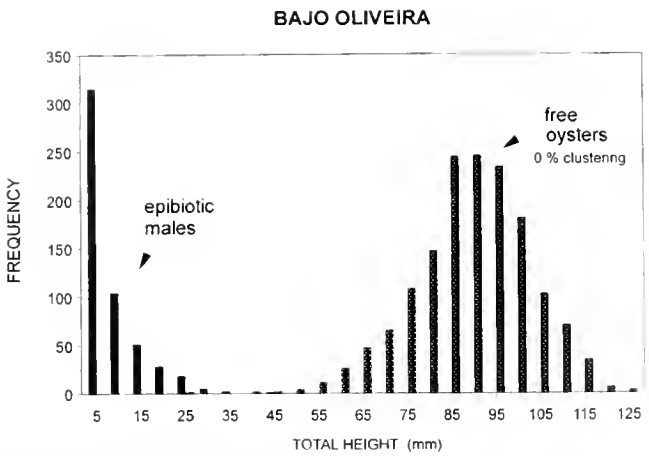

Figure 6. Bajo Oliveira. Complete size structure of the oyster population, including the component represented by dwarf males carried on the platform of carrier oysters. Samples collected on the 1987 survey.

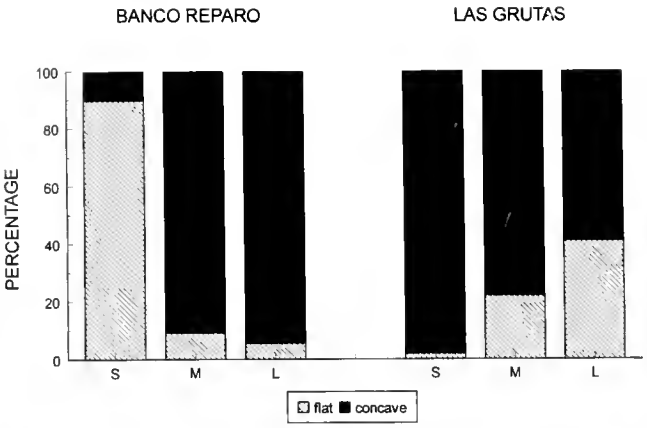

Figure 7. Life position of oysters at Banco Reparo and Las Grutas. Proportion of oysters living with its concave shell up ("concave"), and with its flat shell up ("flat"). Oysters were divided into three size groups: small (S = TH < 3 cm), medium (M = TH = 3–7 cm), and large (L = TH > 7 cm).

mean total height of 89.01 mm (s = 13.39; N = 1550) in 1987, and 90.2 mm (s = 7.52; N = 412) in 1988. The entire population, including epibiotic males, is bimodal (Fig. 6). The mode representing the epibiotic males is 9.09 mm (s = 6.53; N = 532). Carriage levels found on this ground were very high both in 1987 (83.6–97.6%) and in 1988 (74.19–100%). Mean carriage obtained pooling all samples was 88.28% (N = 862). Carrier oysters had a mean of 1.95 epibiotic males per oyster (s = 0.95; N = 151; Table 2) with five the maximum reported. The oysters of Bajo Oliveira are predominantly non-clustered. Pooling all data from 1987, 0% of clustering (N = 302) was found (Fig. 6), and 6.8% in 1988 (N = 560). Total clustering for both surveys was 3.9% (N = 862). All clusters were of two oysters.

The comparison of clustering and carriage percentages between grounds showed significant differences ($P < 0.001$) in all pairs of comparisons, with the exception of the percentages of carriage in Banco Reparo and Las Grutas where no significant differences were detected ($P > 0.001$) (Table 3).

Life position

A total amount of 1,858 oysters were sampled at Banco Reparo, 89.8% were found lying on their flat shell. Life position at this location appears related to the oyster's size with 81.8% of oysters smaller than 3 cm found lying on their concave shell and medium and large oysters (90.8% and 94.4%, respectively) found lying on their flat shell (Fig. 7).

Life position of 1,779 oysters was assessed at Las Grutas, 61% of which were lying on their flat shell. When data were separated by size groups, it was concluded that even when the proportion of oysters lying on their flat shell was higher, the percentages were almost equal in the case of large individuals (Fig. 7).

DISCUSSION

Surveys performed on the three main oyster grounds in the San Matías Gulf (Banco Reparo, Las Grutas and Bajo Oliveira) enabled us to conclude that the puelche oyster is distributed almost continuously along the northern coastal area of the San Matías Gulf, at depths ranging from 2–20 m.

The long planktonic larval life of this species (20 days, Pascual et al. 1989; Pascual and Zampatti 1995) suggests that larvae born in any of the studied grounds are capable of being transported long distances before settling. The grounds or high density areas, are likely interconnected by larval dispersion. This hypothesis rests upon the dynamics of residual coastal currents at the northern portion of the gulf (Lanfredi & Pousa 1988). The main current has two components: one flowing N–NE, and the second, flowing S–SE. The tidal wave follows the shoreline. Banco Reparo and Punta Villarino (Fig. 1) may then act as barriers, forcing the water to circulate describing a clockwise gyre.

The three studied grounds differed in their demographic characteristics. It was difficult to compare the grounds regarding their biomass due to the different assessment methods used. However, the results show that high oyster density areas were not large on any of the grounds, with maximal densities only on relatively small patches.

Oyster size structure at Banco Reparo and Las Grutas was similar. Size classes below 45 mm were better represented at Las Grutas than at Banco Reparo, even when on both grounds individuals <20 mm were not present in the samples. The Bajo Oliveira population showed a different demographic structure; it was represented by very large individuals, with mean size 20 mm larger than on the other two grounds, and no individuals <55 mm. Nowhere did we find patches of recruits, as is the case of other native gulf species such as the scallop, *Aequipecten tehuelchus*, or the mussel, *Mytilus edulis platensis*, suggesting that a clear spatial segregation of settlement does not occur in this species. On all three oyster grounds the portion of the population composing of individuals ranging from 1–30 mm was represented by epibiotic males.

The resulting scenario showed that, in the case of the puelche oyster populations, a distinction should be made between the **apparent demographic structure**, represented by adult and sub adult oysters, and the **real demographic structure**, that includes the small epibiotic oysters, an inconspicuous portion of the population. This "hidden" mode, added to the free portion of the population, shaped the bimodal size distributions typical of these populations. The apparent structure is intriguing in the case of a protan-

dric, sex alternating species, because the portion of the population that is absent, or poorly represented, corresponds to the free males (going through their first sexual maturation). These males are sexually more active than those in which the spermatogenesis occurs as a post-spawning event (females that become males after their first main spawning of the season) (Morriconi & Calvo 1979). In conclusion, the apparent population is primarily female.

The usual life position of free oysters is that in which the flat shell lies against the bottom. This orientation seems to be hydrodynamically more stable, facilitating water flow and minimizing the risk of being drifted by currents. The pattern observed at Banco Reparo, where this life position is exclusive for adult oysters, seems to be adequate for shallow and strong energy environments as an adaptation to resist smothering, condition under which the animals are capable of living for long periods.

Clusters are typical in this species, they are formed by the fixation and subsequent growing of recruits on a "founder" oyster (Morriconi & Calvo 1989). The incidence of this life habit differs among grounds (LG > BR > BO) (Table 3). At Bajo Oliveira, clusters are poorly represented (4%). This gradient among grounds is repeated by the number of oysters forming clusters (LG > BR > BO).

Morriconi and Calvo (1989) compared the incidence of this life habit in the three populations. The gradient that they described is similar to the one reported in this paper, even when the percentages of clustering are lower. This difference could be because their sampling lacked a specific design (Morriconi & Calvo 1989). The collection of samples in some spots of the ground may render a biased image of the overall structure. The authors describe, as well, the sex ratio of free and clustered oysters at Las Grutas, concluding that the proportion of males is higher on clustered (57.9%) than on free oysters (31.6%). This result would be expected if we analyze the size structure of both groups; clusters include a higher proportion of young oysters, ergo, of oysters still in their male protandric sexual phase. This result, however, is difficult to interpret because even when the authors mentioned that they dealt with individuals >50 mm, did not report the size structure of the studied oysters (Morriconi & Calvo 1989).

Here we propose that the different levels of clustering among grounds is a result of other regulatory mechanisms that operate on larval settlement occurring on living oysters, or on the survival of new settlers. These mechanisms, already proven, are mainly grazing (or bulldozing) by chitons, and smothering (Pascual 1997). Grazing accounts for 88% post-settlement mortality (Pascual 1997) of recruits settled on all hard surfaces, in the three months following recruitment. This mechanism, an ecological contingency, may explain the demographic differences among grounds where the mortality agents operate with varying intensity.

The proportion of carrier females is similar at Banco Reparo (32%) and Las Grutas (34%), but is considerably higher at Bajo Oliveira (88%) (Table 3). This topic was previously treated by Morriconi and Calvo (1989), who described the existence of a gradient in carriage, among grounds, inverse to the clustering gradient (LG < BR < BO). This result could again be the result of a biased sampling. The method we used for sample collection was of "total cleaning" of the sample area, thus avoiding bias in the representation of all the size classes present in the population. The similar percentages of carriage in Banco Reparo and Las Grutas are consistent with the similar size structure at both grounds.

The probability of "carrying" epibiotic males increases with the oyster's size. On oysters larger than 50–55 mm, time when carriage of epibiotic males begins, the platform develops, progressively widening. The growth of the epibiotic male produces, additionally, a hollowing on the platform that constitutes, once the epibiotic male detaches, an increasingly favorable substrate for new settlers (Pascual 2000). This development pattern of the platform with oyster size is expressed by the number of epibiotic males carried per oyster: at Banco Reparo and Las Grutas, 61% and 68% of the carriers respectively carry one epibiotic male, while at Bajo Oliveira, 63% of the carrier oysters hold two to five epibiotic males. The high percentage of carriage at Bajo Oliveira may then be explained by the larger size of the individuals that compose this population. The higher number of males per oyster at Bajo Oliveira suggests that recruitment could be heavier at this ground, even when the absence of oysters <55 mm in Bajo Oliveira suggests the opposite. Previous research focusing recruitment patterns on shells and platform of oysters suggest that mortality agents (mainly grazing or bulldozing) strongly operate on recruits at this ground during the three months following recruitment (Pascual 1997, Pascual 2000).

Considering different pieces of information regarding the three studied populations, and even when the age of the oysters cannot be determined in an absolute manner, we are able to conclude that the three populations differ in their dynamics, mainly in the turnover rates of individuals. At Bajo Oliveira, on one extreme, medium size individuals are absent and mean size of adult oysters is highest (89 mm). In comparison, at Las Grutas, intermediate sizes between the two modes are present and the mean size of adults is the lowest (66 mm). Banco Reparo occupies an intermediate position. Turnover rate is then maximal at Las Grutas, intermediate at Banco Reparo, and minimal at Bajo Oliveira.

The puelche oyster grounds at the San Matías Gulf offered the rare opportunity of studying the structure of one of the few natural and untouched flat oyster populations in the world.

The information gathered from the present work and from previous published information, enables us to draw the following scenario:

1. The puelche oyster grounds are mainly composed by low density populations.
2. Turnover rates in the three grounds are low even when Las Grutas shows a relatively higher rate.
3. Adults exert an attraction over the larvae ready to settle, live oysters being the main settlement substrate for oyster larvae in natural grounds (Pascual & Zampatti 1995; Pascual 2000).
4. Post-settlement mortality is very high (95–98%) mainly due to grazing by chitons (Pascual 1997).
5. Growth rate of individuals seems to be very low. The probability of carrying dwarf males on the shell platform increases as the size of the female oyster increases (Pascual 2000).
6. The male portion of the population is mainly represented by the epibiotic males fixed on the platform of female carrier oysters ("a hidden mode").
7. In natural grounds, 33 to 88% of the individuals >55 mm are "long living couples" composed by the female and its epibiotic dwarf male (Pascual et al. 1989).

The existing information provides enough reasons to protect this species, sustaining the fishing closure as a policy mainly based on the vulnerability of the stocks. Commercial exploitation of this species is likely to be supported by aquaculture.

A COMPARATIVE STUDY OF ANTI-*PERKINSUS MARINUS* ACTIVITY IN BIVALVE SERA

ROBERT S. ANDERSON AND AMY E. BEAVEN

Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, P.O. Box 38, Solomons, Maryland 20688

ABSTRACT The eastern oyster *Crassostrea virginica* has been decimated by a protistan parasite *Perkinsus marinus*; however, other bivalves appear to be more resistant to this pathogen. To better understand the basis for this difference in susceptibility, a comparative study of the activities of anti-*P. marinus* serum proteins of several bivalve species was carried out. Sera from mussels not known to develop *P. marinus* disease, *Mytilus edulis* and *Geukensia demissa*, contained high anti-*P. marinus* activity. About 25% of *M. edulis* serum samples contained <10 kDa anti-*P. marinus* peptides; the possibility of seasonal, geographic, or other reasons to explain this variability requires additional study. Anti-*P. marinus* peptides in *G. demissa* serum were apparently absent. Measurable anti-*P. marinus* activity was present in *C. virginica* and *C. gigas* sera, but at levels many hundred-fold lower than that of the mussels. The greater *P. marinus* resistance of *C. gigas* vs. *C. virginica* could not be explained by differences in anti-*P. marinus* activity of their sera. Hemocyte lysates from all the bivalves examined produced marked inhibition of the growth of *P. marinus*, suggesting that antimicrobial agents may be secreted by hemocytes into the serum. These factors may also participate in intracellular destruction of *P. marinus*, since the killing ability of the hemocytes of the different species closely mirrored the anti-*P. marinus* activities of their sera. The data suggest that *C. virginica* lacks active anti-*P. marinus* serum agents typical of *M. edulis* and *G. demissa*; however, *P. marinus* resistance of *C. gigas* seems not to depend upon elevated levels of antimicrobial serum factors.

KEY WORDS: *Perkinsus marinus, Crassostrea virginica, Crassostrea gigas, Geukensia demissa, Mytilus edulis*, antimicrobial proteins, defensins

INTRODUCTION

Circulating hemocytes form the basis for host defense in bivalve mollusks and many other invertebrates. Typically these cells mediate the destruction of foreign microorganisms encountered by chance contact in the hemolymph, or as a result of chemotactic migration (Cheng & Howland 1979). The microbes can be killed intracellularly or extracellularly by a variety of cytotoxic factors released from the cells. Many cytotoxic molecules have been described in the hemocytes and sera of bivalves such as lysosomal hydrolases (Pipe 1990) particularly lysozyme (McDade & Tripp 1967, Hardy et al. 1976), reactive oxygen species (Adema et al. 1991, Anderson 1996), reactive nitrogen species (Conte & Ottaviani 1995), as well as antimicrobial proteins and peptides (Roch et al. 1996). These activities may be constitutive, or may be stimulated or suppressed by various treatments. Furthermore, the expression of particular cytotoxic agents in bivalves can differ between species (Anderson 1994), seasons of the year (Santarém et al. 1994), and geographic locations (Fisher et al. 1996). Bivalves are generally able to mount an adequate defense against a majority of microbial invaders, thereby containing or resolving infections by evoking several complementary mechanisms of innate immunity. However, some pathogenic species, such as *Perkinsus marinus*, can subvert or escape these defense mechanisms in their susceptible bivalve hosts.

A number of small, cationic, cysteine-rich antimicrobial peptides have been described in bivalve mollusks, especially mussels. *Mytilus galloprovincialis* serum contains MGD1, a 4.4 kDa defensin-like peptide with 8 cysteines in its primary structure (Hubert et al. 1996a). Another isoform (MGD2) has recently been described, and both peptides are abundantly expressed in hemocyte granules (Mitta et al. 1999b). Bacterial challenge triggers release of MGD1 by the hemocytes into the cell-free hemolymph or serum (Mitta et al. 1999b). Peptides resembling arthropod defensins, with sequence similarities and 6 cysteines (defensins A and B) exist in the hemolymph of *Mytilus edulis* (Charlet et al. 1996). Another group of 4 kDa antimicrobial peptides have been found in mussels that are distinct from defensins; to date 5 isoforms are known: mytilins A and B from *M. edulis* (Charlet et al. 1996), and mytilins C, D and G1 from *M. galloprovincialis* (Mitta et al. 2000). Experimentally unchallenged *M. galloprovincialis* hemocytes and plasma contain other novel ~4 kDa antibacterial peptides (myticin A and B) containing 8 cysteines (Mitta et al. 1999a). In addition to these antibacterial molecules of mussels, an antifungal peptide of 6.5 kDa containing 12 cysteines was found in *M. edulis* serum (Charlet et al. 1996). Knowledge of antibacterial peptides of oysters and other bivalves is quite minimal. Antibacterial activity associated with small proteins or peptides was found in hemocytes and serum of *Ostrea edulis* and *Crassostrea gigas* (Hubert et al. 1996b).

The presence of lysozyme-like activity in bivalve hemolymph has been known for many years (McDade & Tripp 1967); it is another hemocyte-produced antimicrobial agent that can be released into the serum during bacterial challenge (Cheng et al. 1975). Lysozyme is thought to function in self-defense because it induces bacterial cell lysis by hydrolyzing β-1, 4 linked glycosidic bonds of cell wall peptidoglycan. Activities of bivalve lysozymes are often initially measured against *Micrococcus luteus*, although they are active against many other Gram-positive, as well as Gram-negative, bacteria. The approximate molecular mass of bivalve lysozymes range from 11 kDa (Nielsen et al. 1999) to 18 kDa (McHenry & Birckbeck 1979); they are thought to belong to a distinct family of invertebrate lysozymes (Jollès et al. 1996). Recently two molecules with lysozyme-like activity against *M. luteus* have been purified and characterized from bivalves: a 13 kDa protein with as many as 14 cysteine residues from *Tapes japonica* (Ito et al. 1999), and a 11 kDa enzyme (chlamysin) from the Icelandic scallop *Chlamys islandica* (Nilsen et al. 1999). The enzymes showed high protein structure stability and had high sequence homology to each other, but not to other known types of lysozyme.

A larger (320 kDa) cytotoxic polymeric protein has been described in *M. galloprovincialis* (Hubert et al. 1996b). It polymerizes to form a lytic complex that can disrupt the membranes of mammalian erythrocytes, mouse myeloma cells, and can kill

Bonamia ostreae, a protozoan parasite of the oyster *Ostrea edulis*. However, several bacterial species seem unaffected by this protein. This lytic activity in the plasma could be stimulated by sham injection or by injection of erythrocytes (Hubert et al. 1997).

The protistan parasite, *Perkinsus marinus*, is a major pathogen of the eastern oyster, *Crassostrea virginica*, causing mass mortalities in the Gulf of Mexico and the Chesapeake Bay. However, it is relatively nonpathogenic for other bivalves, including some species that share the same habitat with highly infected oysters. In order to better understand the basis for this marked difference in susceptibility, the results of comparative studies of anti-*P. marinus* serum proteins and peptides in several bivalve species are reported in this study.

MATERIALS AND METHODS

Bivalves

Local eastern oysters, *Crassostrea virginica*, were obtained from a commercial supplier; they originated from the Wicomico and/or St. Mary's Rivers, Maryland. Eastern oysters from Maine were purchased from the Pemaquid Oyster Company (Waldoboro, ME), and were collected in the Damariscotta River. *Crassostrea gigas* were purchased from the Taylor Shellfish Company (Shelton, WA), and had been collected from Totten Inlet, Puget Sound. Ribbed mussels, *Geukensia demissa*, were collected at Chincoteague, VA. *Mytilus edulis* were obtained at a local food store (their original source was Tenants Harbor, ME), collected by diving off Ocean City, MD, purchased from the Marine Biological Laboratory (Woods Hole, MA), or purchased directly from Great Eastern Mussel Farms (Tenants Harbor, ME).

The bivalves were held in aerated, recirculated water systems at 12 C, containing 25 ppt Instant Ocean (Aquarium Systems, Inc., Mentor, OH). Levels of nitrate/nitrite and ammonia were monitored and full or half water changes made whenever these parameters were outside the normal range. Bivalves were routinely acclimated in the tanks for at least one week before experimentation. The animals were fed live cultured algae or reconstituted frozen algal slurry 5 days per week. The live algae was a mixture of *Isochrysis galbana* and *Thalassiosira weissflogii*; the frozen slurry contained *Isochrysis* sp., *Chaetocerus gracilis*, and *Tetraselmis* sp.

Cultivation of Perkinsus marinus

Perkinsus marinus (strain I) cultures were originally provided by Drs. M. Faisal and J. La Peyre (Virginia Institute of Marine Science). The cultures were maintained in DME/HAM F-12 medium, with phenol red, reconstituted with 10 ppt artificial sea water and contained 1% penicillin-streptomycin solution, 2% fetal bovine serum, and was HEPES-buffered at pH 6.5. All the components of the medium were purchased from Sigma Chemical Co. This medium is a modification of that originally described by Gauthier and Vasta (1993).

*Anti-*Perkinsus marinus *Activity of Sera and <10 kDa Peptides*

Samples were withdrawn from the adductor muscle hemolymph sinus with a syringe equipped with a 1.5 inch 22 gauge needle. Samples were pooled from ≥6 bivalves and held at 1°C prior to centrifugation (300 *g*, 10°C, 10 min) to separate the hemocytes from the serum. The supernatant (serum) was filter-sterilized by passage through a 0.2 μm Whatman Puradisc syringe filter and frozen (−20°C) until further use, the cell pellet was discarded. Subsequently, the protein content of the serum was measured (BCA protein assay kit, Pierce Co.) and the desired concentrations reached by dilution with filter-sterilized Instant Ocean sea salts (Aquarium Systems, Inc.), adjusted to 25 ppt salinity (IO). Cultured *P. marinus* cells were washed and resuspended at a known density in DME/HAM F-12 media without phenol red, this *P. marinus* suspension was mixed with a dilution of serum to give a known final concentration of serum protein containing 1×10^5 *P. marinus* cells per ml, and incubated at 26°C. Sterile technique was used throughout all experiments. As indicated on the Figures, 0.5 ml aliquots were periodically removed from the culture flasks and read at 560 nm in a spectrophotometer; these OD readings were converted to numbers of *P. marinus* cells/ml from a previously constructed standard curve. In this way, the effects of various serum concentrations on the growth kinetics of this protistan were determined. This same basic method was also used to obtain a measurement of relative anti-*P. marinus* activity in the sera of the bivalve species under study. *P. marinus* cultures, set up as described, were in active growth phase for at least 200 h; exposure to serum during this period often markedly inhibited this growth. Therefore, the Ab_{560} of 170-hour cultures exposed to various serum concentrations were compared to the 170-h Ab_{560} of serum-free controls to determine the concentration of serum proteins required for 50% inhibition of normal growth (EC_{50}).

The anti-*P. marinus* activity of <10 kDa serum peptides was measured by the same turbidometric assay by substituting these peptides for the serum samples. About 9 ml of pooled, filter-sterilized bivalve serum was separated by ultrafiltration with Millipore Ultrafree Protein Concentrators by passage through 100 kDa and 10 kDa exclusion filters. Molecules passing through the 10 kDa ultrafilter were tested for anti-*P. marinus* activity. Preliminary data suggest that this activity may be lost after ≥1 month storage at −20°C.

Lysozyme Activity

Lysozyme activity was expressed as egg white lysozyme equivalents. Lysozyme dilutions (0–20 μg/ml) were prepared in 0.05 M HEPES buffer, pH 6.8. These standard solutions (0.25 ml) were mixed with 2.0 ml *Micrococcus lysodeikticus* (*M. luteus*) cell wall preparations (0.01 g/50 ml 0.05 M HEPES buffer) in order to produce a lysozyme standard curve. The ΔOD_{540}/min for each lysozyme concentration was measured spectrophotometrically. The resultant linear relationship between cell wall lysis and lysozyme concentration was used to quantify lysozyme levels in bivalve sera or <10 kDa peptides.

Inhibition of Perkinsus marinus *Cultures by Hemocyte Extracts*

Hemocytes were separated from hemolymph by centrifugation (300g, 10°C, 10 min), washed with IO, frozen at −20°C and thawed. Freeze-thawing was carried out three times, the lysate centrifuged (300g, 10°C, 10 min), and the cell debris pellet discarded. The supernatant was filtered (0.2 μm), analyzed for protein, permitting aliquots of known protein concentration to be added to *P. marinus* cultures; their effects on *P. marinus* growth at 170 hours were measured as described above.

*Anti-*P. marinus *Activity of Hemocytes*

This procedure was adapted from a tetrazolium dye assay used to assess the bactericidal activity of oyster hemocytes (Volety et al. 1999). Aliquots from 4–7d *P. marinus* cultures were centrifuged

and resuspended in ~0.4 original volume 25 ppt Instant Ocean containing 1% penicillin/streptomycin solution (IO/PS). The *P. marinus* density in this suspension was determined in a hemacytometer and adjusted to 1.2×10^7 cells/ml. Bivalve hemocytes were obtained and processed as previously described (Anderson et al. 1992), and a suspension of 2×10^6 hemocytes/ml was prepared. A 96-well microtiter plate was set up as follows: row one: 75 µl IO/PS, row two: 50 µl hemocytes and 25 µl IO/PS, row three: 50 µl hemocytes and 25 µl *P. marinus* (final ratio was 3 *P. marinus*/hemocyte), and row four: 50 µl IO/PS and 25 µl *P. marinus*. Different cell pools were used in each of 3 experiments, with 6 replicate wells for each experiment. The microtiter plate was incubated at room temperature (~21° C) for 2.5 h to permit cellular killing of the parasites. All wells then received 100 µl of DME/HAM F-12 medium without phenol red, and the plate was incubated (26° C, 17h) to provide a grow-out period for the surviving *P. marinus*. Then 20 µl MTS/PMS solution was added to all wells, following the directions for the Cell Titer 96 Aqueous Cell Proliferation Assay Kit (Promega Co.); the plate was vortexed and incubated an additional 2 h at 26° C. The absorbency of the wells was measured at 490 nm on a SpectraCount Plate Reader (Packard). The absorbance values of the reagent blanks (row 1) were subtracted from the readings of the wells in rows 2–4 to give corrected (corr) values and a killing index (KI) was calculated by the formula:

$$KI = 1 - \left(\frac{Abs\ row\ 3\ corr. - Abs\ row\ 2\ corr.}{Abs\ row\ 4\ corr.} \right) \times 100$$

RESULTS

Effect of Sera on Growth of Perkinsus marinus

At the seeding densities used in these studies, *P. marinus* cultures showed rapid growth from ~70–200 hr. The presence of *M. edulis* serum in the culture medium reduced *P. marinus* growth in a dose-dependent manner from 2–40 µg serum protein/ml DME-HAM medium (Fig. 1A). *G. demissa* serum was even more effective, with 20 µg /ml completely inhibiting growth for at least 200 hours (Fig. 1B). However, initial experiments using ≥600 µg/ml local *C. virginica* serum had an insignificant effect on *P. marinus* growth (data not presented).

*Comparison of Anti-*Perkinsus marinus *Activities*

The concentrations of serum proteins in *P. marinus* growth medium required to reduce the normal growth of the culture at 170 hr by 50% (EC_{50}) was determined for each bivalve. At 170 hr, normal growth was exponential and any serum-related inhibitory effects were evident (Fig. 1). Comparatively weak anti-*P. marinus* activity could be detected in the sera of *C. virginica* and *C. gigas* (Fig. 2). The EC_{50}s for locally collected *C. virginica*, Maine *C. virginica*, and *C. gigas* were ~2, 0.7, and 1.4 mg/ml, respectively. As was predicted from the preliminary observations (Fig. 1), the anti-*P. marinus* activity of mussel sera greatly exceeded that of oyster sera: *M. edulis* and *G. demissa* EC_{50}s were ~7 and 3 µg/ml, respectively (Fig. 3).

The <10 kDa serum peptides from local *C. virginica*, *M. edulis* and *G. demissa* were tested for anti-*P. marinus* activity. Such activity was never seen in peptides from *C. virginica* or *G. demissa*; however, about 25% of the *M. edulis* <10 kDa fractions tested showed comparatively strong anti-*P. marinus* activity (56.7 ± 11.2% growth inhibition). Lysozyme activity was also determined in serum and <10 kDa peptides from these bivalves. Lysozyme levels in *C. virginica* serum were high (20.3 ± 2.3 µg/ml) as comparted to those in *M. edulis* (1.4 ± 0.7) and *G. demissa* (3.9 ± 0.6). Some lysozyme-like activity was recorded for the <10 kDa fraction from *C. virginica*, but only trace levels were seen in the peptides of *M. edulis* (0.02 ± 0.08) or *G. demissa* (0.11 ± 0.13).

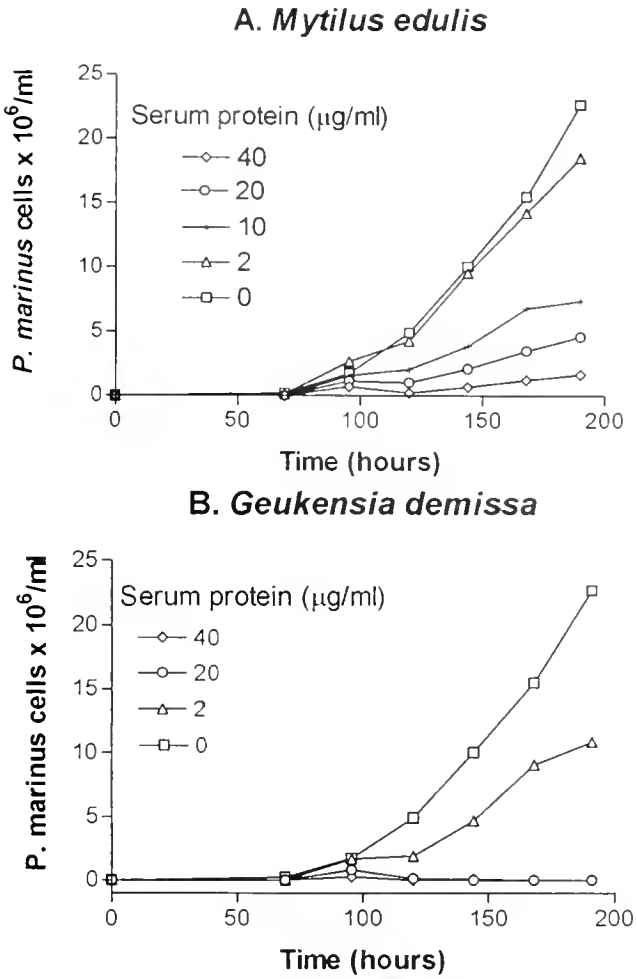

Figure 1. The effect of the presence of mussel sera on the growth of *P. marinus*. Growth kinetics were inhibited by ≤40 µg/ml serum proteins from *M. edulis* (A.) and *G. demissa* (B.)

Inhibition of Perkinsus marinus *Growth by Hemocyte Extracts*

Anti-*P. marinus* activity was also present in the hemocytes of the bivalves in this study (Fig. 4). Protein extracts from these cells markedly inhibited the growth of *P. marinus* cultures, especially lysates from *M. edulis* and *G. demissa*. The activity of *C. virginica* (local) hemocytes was somewhat lower, but apparently greater than that of the serum, on a per µg protein basis.

Hemocyte-mediated Killing of Perkinsus marinus

Laboratory-propagated *P. marinus* was actively killed *in vitro* by hemocytes of the mussels (*G. demissa* and *M. edulis*); however, both local and Maine *C. virginica* and *C. gigas* hemocytes showed much lower and more variable killing ability (Fig. 5). Anti-*P.*

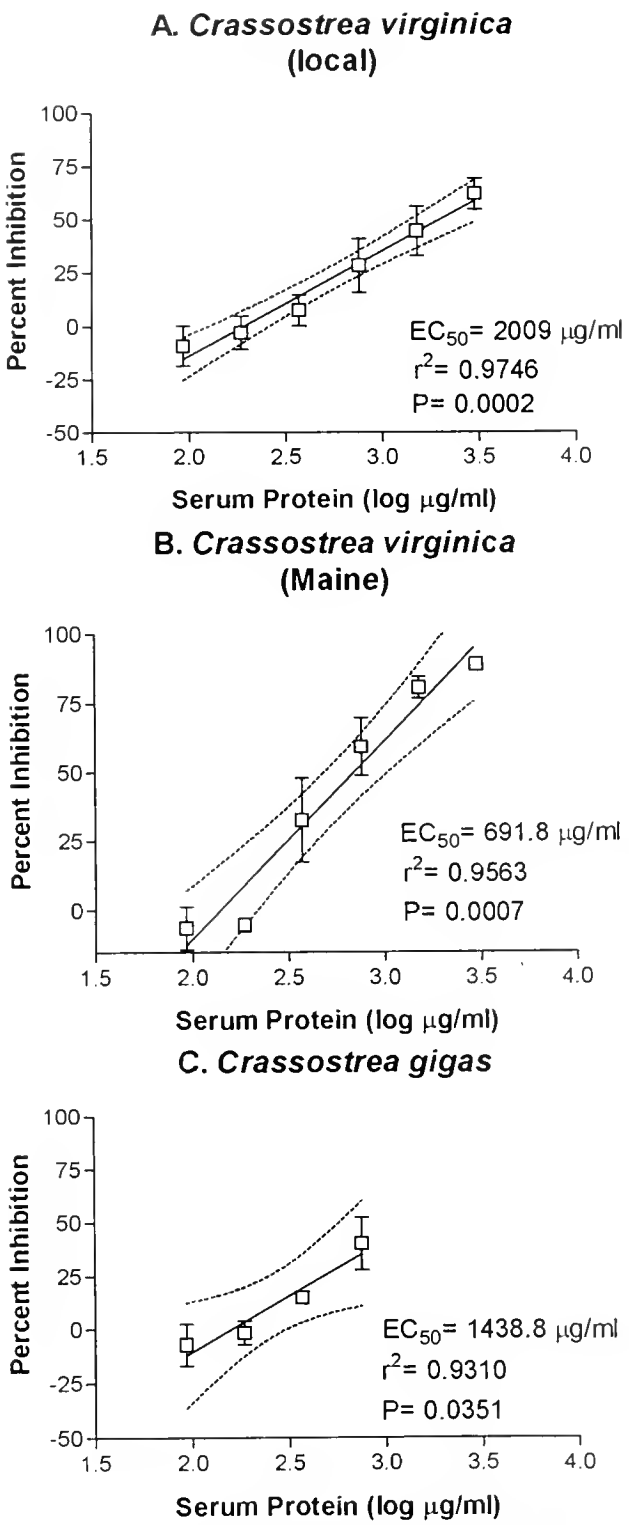

Figure 2. Dose-dependent inhibition of *P. marinus* by oyster sera: Maryland *C. virginica* (A.), Maine *C. virginica* (B.), and *C. gigas* (C.). The EC_{50} values represent the mean µg oyster serum protein/ml medium (n = 5) required to reduce normal *P. marinus* growth at 170 hr by 50%.

marinus capacity of hemocytes from the mussel species was significantly greater than that of the oysters ($P < 0.05$, Students *t* test). The cellular pattern of activity mirrored that of the hemocyte extracts.

DISCUSSION

In order to learn more about the basis for the differential resistance to the *C. virginica* pathogen *P. marinus* shown by other bivalves, a comparative study of cytotoxic serum proteins and peptides was carried out. The species selected include local *C. virginica* with light-moderate *P. marinus* infections, uninfected Maine *C. virginica* that were minimally exposed to *P. marinus in situ*, *C. gigas* that are reported to be more resistant to *P. marinus* disease than *C. virginica* (Meyers et al. 1991), and two mussels *M. edulis* and *G. demissa* that may be naturally exposed to *P. marinus*, but develop few pathological consequences. Progression of any *P. marinus* infections in oysters in these studies was retarded by maintenance at 12°C. In this study, the bivalves were not treated in any way to experimentally modulate the activity of naturally-occurring anti-*P. marinus* serum factors. However, it is possible that collecting, laboratory maintenance, infection of oysters by *P. marinus*, and/or infection of the bivalves by other microorganisms could have influenced the levels present in the sera. In light of the reported inducibility of many antimicrobial substances, experiments are planned to quantify the effects of *P. marinus* infection and other stressors on the expression of cytotoxic proteins and/or peptides.

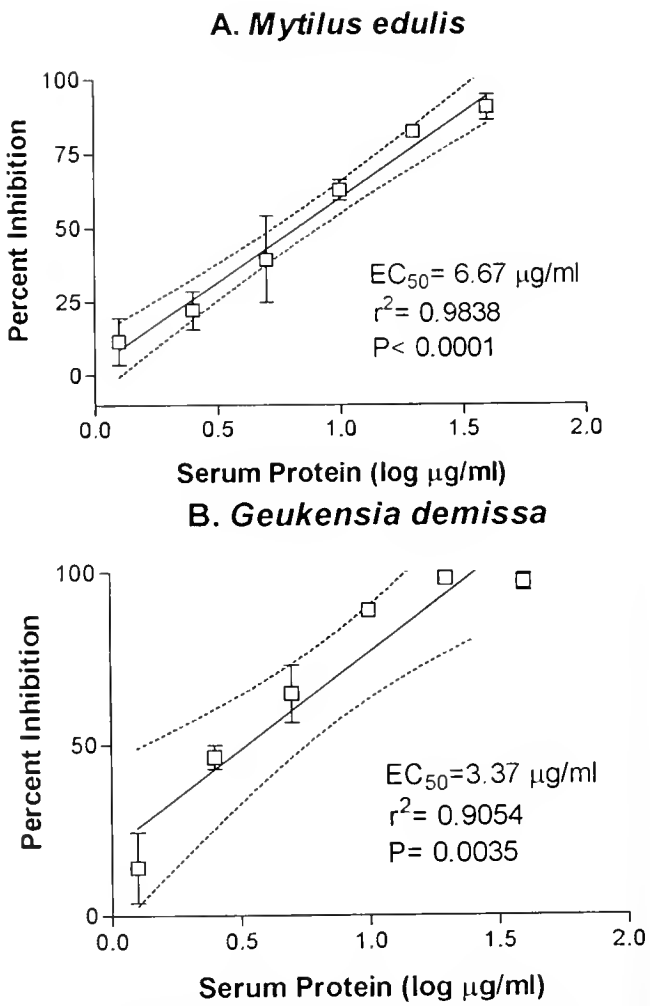

Figure 3. Dose-dependent inhibition of 170 hr *P. marinus* cultures by serum proteins from *M. edulis* (A.) and *G. demissa* (B.). The EC_{50} values are calculated as described for Figure 2.

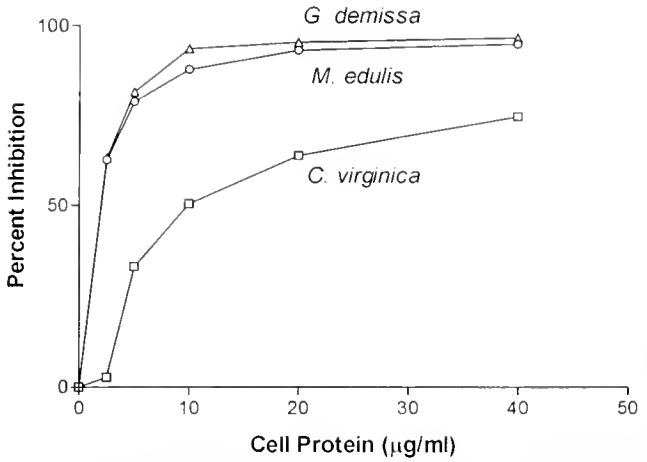

Figure 4. Inhibition of 170 hr *P. marinus* cultures by hemocyte lysates from *G. demissa*, *M. edulis*, and local *C. virginica*; hemocyte lysates from Maine *C. virginica* and *C. gigas* were not analyzed.

The mussel sera had many hundred-fold greater anti-*P. marinus* activity than *C. virginica* sera; this might be expected because of their apparently greater resistance to the parasite, since they are rarely infected. Antimicrobial molecules in *M. edulis* and *M. galloprovincialis* are well known (see Introduction), but this is the first report of such activity in *G. demissa*. As little as ~7 μg/ml *M. edulis* serum protein could inhibit *P. marinus* growth by 50%, *G. demissa* serum was about twice as active. By comparison, about 2 mg/ml local *C. virginica* serum was required to produce comparable inhibition of *P. marinus*. It is interesting that anti-*P. marinus* activity of *C. gigas* serum was slightly, but not statistically significantly, more active than local *C. virginica*. The possible role of serum factors in *C. gigas* resistance to *P. marinus* has not been clarified. The apparently higher anti-*P. marinus* activity of sera from Maine oysters versus local oysters is also hard to explain. In Maine, oysters are rarely infected by *P. marinus* probably because of its geographic location near the Northern range of the parasite. The lower anti-*P. marinus* activity in local oysters may be a consequence of, or a contributing factor to, their *P. marinus* infections, or a reflection of strain differences in oysters collected from distant sites.

The <10 kDa fractions of the sera are of interest because in these would be found defensins or other antimicrobial peptides. There was no evidence of anti-*P. marinus* activity in this fraction of *C. virginica* or *G. demissa* serum, but high activity was occasionally seen in the <10 kDa *M. edulis* fraction. This implies that different molecules are involved in the strong anti-*P. marinus* activities of the two mussels. The activity of *Mytilus* spp. antimicrobial peptides against protistan parasites has received comparatively little study. The inhibitory activity of *M. edulis* serum was first noted by Gauthier (1998). MGD-1, a defensin from *M. galloprovincialis* was found to be inactive against *P. marinus* (Hubert et al., 1996a), but the other molluscan peptides have not been assayed for anti-protistan activity. However, antimicrobial peptides from other animals have shown this activity: megainin 1 (from the skin of *Xenopus laevis*) killed *Bonamia ostreae*, the intrahemocytic parasite of the oyster *Ostrea edulis* (Morvan et al. 1994) and polyphemusin (from hemocytes of *Limulus polyphemus*) inhibited growth of *Perkinsus marinus* at 8 μg/ml (Pierce et al. 1997). Both of these authors have considered the possibility of using genes coding for antimicrobial peptides to produce disease-resistant, transgenic mollusks; this possibility has also been discussed by Roch (1999).

In *C. virginica* serum lysozyme levels were comparatively high (~20 μg/ml), but its putative role in anti-*P. marinus* defense has yet to be definitively established. Chu and La Peyre (1989) reported low levels of lysozyme activity in Chesapeake Bay oysters in the summer, when levels of *P. marinus* infection are high, but Fisher et al. (1996) found the opposite for oysters from Florida. Reports on lysozyme levels as influenced by *P. marinus* infection in field-collected oysters are conflicting, but experimental infection has little effect on levels of the lysozyme in *C. virginica* or *C. gigas* (La Peyre et al. 1995). While there is little doubt that lysozyme in bivalve sera plays a protective role by virtue of its antibacterial activity, there are several lines of evidence to diminish the likelihood that it has much effect against *P. marinus*. *C. gigas* is more resistant to *P. marinus* than *C. virginica*; however, lysozyme levels in *C. virginica* are much higher than *C. gigas* (La Peyre et al. 1995). The same conclusion can be drawn from the data in this study, where the anti-*P. marinus* activities of *M. edulis* and *G. demissa* sera are many hundred-fold that of *C. virginica*, but the lysozyme levels are quite low in the mussels as compared to the oyster. It appears that the agent(s) in *M. edulis* and *G. demissa* serum responsible for anti-*P. marinus* activity have yet to be identified. The data above suggests that lysozyme may not be important. Likewise, antimicrobial peptides may not contribute much to the anti-*P. marinus* activity of mussel sera. No anti-*P. marinus* activity was ever detected in the <10 kDa fraction of *G. demissa* serum and such activity was only occasionally seen in *M. edulis* peptides, but all unseparated mussel serum samples had very high anti-*P. marinus* activity, regardless of the presence or absence of active peptides.

In addition to serum components such as antimicrobial peptides, lysosomal hydrolases, and recognition factors, the 320 kDa cytotoxic polymeric protein described by Hubert et al. (1996b) in *M. galloprovincialis* serum will be looked for in future studies. This seems like a particularly promising candidate for an anti-*P. marinus* protein in light of its activity against *Bonamia ostreae*.

When hemocytes from the oysters and mussels in this study were lysed, comparatively high levels of anti-*P. marinus* activity could be measured (Fig. 4). The activities of *M. edulis* and *G. demissa* hemocyte extracts were higher than that of *C. virginica* (local). These data suggest that the agents responsible for anti-*P.*

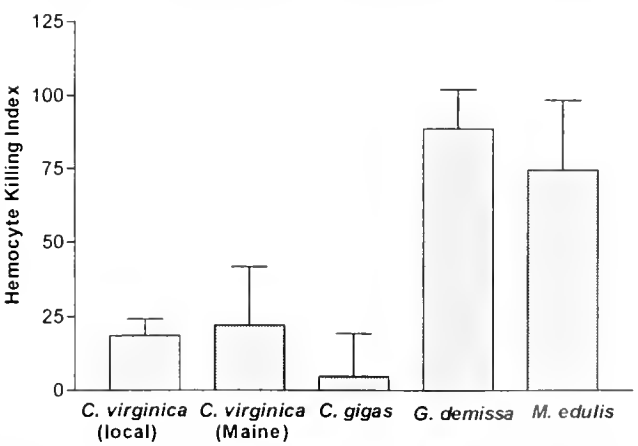

Figure 5. The *in vitro* ability of oyster and mussel hemocytes to kill *P. marinus*. Height of the bars indicate mean % *P. marinus* killed in 2.5 hr ± SD, n = 4.

marinus activity in the sera probably are synthesized by and released from the hemocytes, as is the general case for bivalves (Cheng 1992, Mitta et al. 1999b). The mussels >oysters pattern of anti-*P. marinus* activity seen in the sera and cell extracts was also recorded when the ability of hemocytes to kill *P. marinus* in vitro was tested (Fig. 5). *C. virginica* hemocytes were able to kill ~25% of the parasites and *C. gigas* hemocytes killed ~10%, but there was considerable variation and no significant differences between the oyster hemocyte killing indices. Since *C. virginica* has very limited ability to destroy *P. marinus* in vivo, it was surprising that a modest hemocyte killing index was consistently recorded. A similar finding was reported by Volety and Fisher (2000), in which hemocytes from Floridian oysters averaged 57% *P. marinus* killing capacity. Since it is likely that *P. marinus* loses some of its virulence during laboratory culture (Bushek et al. 1997); it would be interesting to test the ability of hemocytes to kill *P. marinus* freshly harvested from naturally infected oysters. In any case, it appears that resistance of *C. gigas* to *P. marinus* cannot be explained by enhanced capacity for hemocytic killing. In contrast to the oysters, *G. demissa* and *M. edulis* cells routinely and efficiently destroyed *P. marinus in vitro*.

In conclusion, the data suggest that low-level anti-*P. marinus* activity can be detected in the serum and cells of *C. virginica* and *C. gigas*, but differences between these species are insignificant and cannot be used to explain reported differences in resistance to *P. marinus* disease. However, the serum and cells of the mussels *G. demissa* and *M. edulis* have high levels of anti-*P. marinus* activity. In all bivalve species tested, the hemocytes contained anti-*P. marinus* activity, and it is likely that the hemocytes secrete serum antimicrobial agents. It appears that the high anti-*P. marinus* activity characteristic of *M. edulis* and *G. demissa* sera may depend on cytotoxic molecules other than, or in addition to, lysozyme or antimicrobial peptides.

HISTOPATHOLOGY OF THE INFECTION BY *PERKINSUS ATLANTICUS* IN THREE CLAM SPECIES (*RUDITAPES DECUSSATUS*, *R. PHILIPPINARUM* AND *R. PULLASTRA*) FROM GALICIA (NW SPAIN)

M. CAMINO ORDÁS, J. GOMEZ-LEON, AND ANTONIO FIGUERAS*

Instituto de Investigaciones Marinas, Consejo Superior de Investigaciones Científicas (CSIC), Eduardo Cabello 6, 36208 Vigo, Spain

ABSTRACT In this study, we have determined the histopathology of the infection by the protozoan parasite *Perkinsus atlanticus* in three exploitable clam species (carpet-shell clam *Ruditapes decussatus*, Manila clam *R. philippinarum*, and the species *R. pullastra*) from Galicia (NW of Spain). In histological preparations from infected animals, typical mature trophozoites of *Perkinsus*, containing lipid droplets and vacuole but no vacuoplast, were observed. The trophozoites were usually in groups surrounded by a light halo. Pre-palintomic tomonts, as well as palintomic tomonts with a variable number of daughter cells, were also present in the host tissues. Less frequently, immature trophozoites with an undifferentiated cytoplasm were observed. The presence of *P. atlanticus* cells was always associated with a strong hemocytic infiltration of the surrounding tissues. Occasionally, the parasite cells were internalized by granular hemocytes. The morphology and distribution of the *P. atlanticus* were similar in the three clam species studied, this being the first time that *R. pullastra* from Galicia has been found infected by *P. atlanticus*. The morphology of the parasite's life cycle stages and the histopathology of the infection resemble those reported on other species of the genus *Perkinsus*.

KEY WORDS: *Perkinsus atlanticus*, protistan, Protozoa, *Ruditapes decussatus*, *Ruditapes philippinarum*, *Ruditapes pullastra*, histopathology

INTRODUCTION

Protozoan parasites of the genus *Perkinsus* (Apicomplexa, Perkinsea) have been reported from marine molluscs all around the world. *P. marinus* (Mackin et al. 1950) has been associated with heavy oyster mortalities in the East and Gulf coasts of the USA since it was first described (Andrews 1996, Burreson et al. 1994). *P. olseni* parasitizes the abalone (*Haliotis ruber*) in Australia (Lester & Davis 1981), and the recently described *P. qugwadi* infects the Japanese scallop (*Patinopecten yessoensis*) in Canada (Blackbourn et al. 1998). Until now, the only *Perkinsus* species described in Europe has been *P. atlanticus*, parasite of the carpet-shell clam (*Ruditapes decussatus*) in Portugal (Azevedo 1989). On the other hand, *Perkinsus* sp. infections have been described in Manila clam (*Ruditapes philippinarum*) from Japan (Hamaguchi et al. 1998, Maeno et al. 1999) and Korea (Choi & Park 1997), in the pearl oyster (*Pinctada maxima*) and 30 other molluscan species from Australia (Goggin & Lester 1987, Norton et al. 1993), and in more than 30 marine bivalve species in different areas of the Pacific and Atlantic oceans (Perkins 1988).

In Spain, *Perkinsus* sp. has been found in the carpet-shell clam (*Ruditapes decussatus*) and the Manila clam (*R. philippinarum*) from the South Atlantic, Mediterranean and Cantabric coasts (Cigarría et al. 1997, Montes et al. 1995a, Navas et al. 1992, Sagristà et al. 1995). Two other bivalve molluscs of economical importance, *R. pullastra* and *Venerupis aureus*, have been reported to be infected by this parasite in Huelva (SW Spain) (Navas et al. 1992).

In Galicia (NW Spain), clam aquaculture is an activity of high economical importance. The production of *Ruditapes decussatus*, *R. pullastra* and *R. philippinarum* in this region in 1998 totaled 914, 2554 and 604 Tm respectively, this representing an annual income of approximately 4900 million pesetas (1 US$ = 185 pesetas) (data from the Consellería de Marisqueo, Pesca y Acuicultura of the Xunta de Galicia). The presence of a *Perkinsus*-like organism was associated with severe carpet-shell clam mortalities in a depuration plant in Meira (Galicia) thirteen years ago (Figueras et al. 1992, González Herrero et al. 1987). Later, *Perkinsus* sp. was detected in carpet-shell clams and Manila clams from different locations along the Galician coast (Figueras et al. 1996). A strong hemocytic infiltration was always observed in the *Perkinsus*-infected tissues, this probably affecting the clam health and endangering its production (Figueras et al. 1992). Recently, Novoa et al. (2001), using molecular tools based on the 18S rRNA gene, have demonstrated the identification of the *Perkinsus* species observed in carpet- shell clams from Galicia as *P. atlanticus*.

This study was conducted to describe the histopathology of the *Perkinsus atlanticus* infection in the three economically most important clam species in Galicia: carpet-shell clam, Manila clam and *R. pullastra*.

MATERIALS AND METHODS

Clams

Market-sized carpet-shell clams (*Ruditapes decussatus*), Manila clams (*R. philippinarum*) and R. *pullastra*, were collected in Campelo (Ría of Pontevedra), Meira, Vilaboa and Arcade (all Ría of Vigo), and Camariñas (Central Ría) (all Galicia, NW Spain) (Fig. 1). Approximately, one hundred individuals were examined from each location. The animals were processed immediately after being received in the laboratory.

Diagnosis of Perkinsus

The presence of *Perkinsus atlanticus* infection in the clams was assessed using Ray's Fluid Thioglycollate Medium (RFTM). Briefly, one pair of gills from each clam was introduced into Fluid Thioglycollate Medium (FTM) (Ray 1954, Ray 1966), and incubated at room temperature in the dark for three to five days. Then,

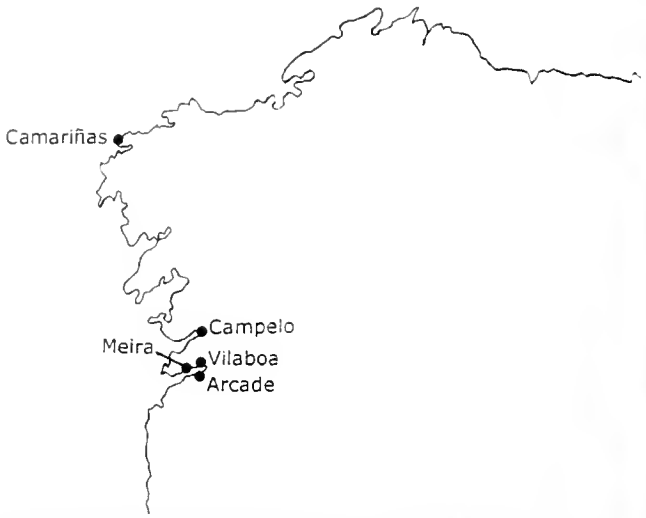

Figure 1. Clam sampling sites in the Ría of Pontevedra (Campelo), Ría of Vigo (Meira, Vilaboa and Arcade) and Central Ría (Camariñas), all of them located in Galicia (NW Spain).

gills were placed on a slide, stained with Lugol's iodine and observed with a light microscope.

Histology

The remaining soft tissues were fixed in Davidson's fixative (Shaw & Battle 1957) for 24 hours and a transverse section approximately 5 mm thick including mantle, gonad, digestive gland, gills, kidney, and foot, was excised from each clam. Tissue samples were embedded in paraffin and 5-µm sections were stained with hematoxylin-eosin. The histological sections were observed under a light microscope (Nikon).

RESULTS

The RFTM-treated gills of several carpet-shell clams, Manila clams and *R. pullastra* showed dark blue spherical bodies, typical of hypnospores of *Perkinsus*. Only those clams diagnosed as positive for *Perkinsus* by RFTM were examined histologically.

Macroscopically, the most heavily infected individuals showed milky-white cysts in their body surface. Under the microscope, the morphology and distribution of *Perkinsus atlanticus* life cycle stages in the host tissues were similar in the three clam species studied, with strong hemocytic infiltration of the infected tissues and encapsulation of the parasite (Fig. 2, Fig. 3, Fig. 4). The histopathology of the infection by *P. atlanticus* in *Ruditapes decussatus* is described in detail below.

The parasite cells were mainly located in the gills and connective tissue close to the digestive epithelium and digestive tubules (Fig. 4A). In heavy infections, the parasite was detected in all clam organs examined, including the gonads and the muscle tissues (Fig. 4B). Granular hemocytes containing one (Fig. 5A) to ten (Fig. 5B) *P. atlanticus* cells were frequently observed.

The most prevalent *P. atlanticus* life cycle stage present in the clam tissues was the mature trophozoite (Fig. 6). Its large eccentric vacuole lacked a vacuoplast, and a dark nucleolus was present inside the nucleus (Fig. 6C). The trophozoites were usually grouped in clumps of 2 to 20 cells that were usually similar in size

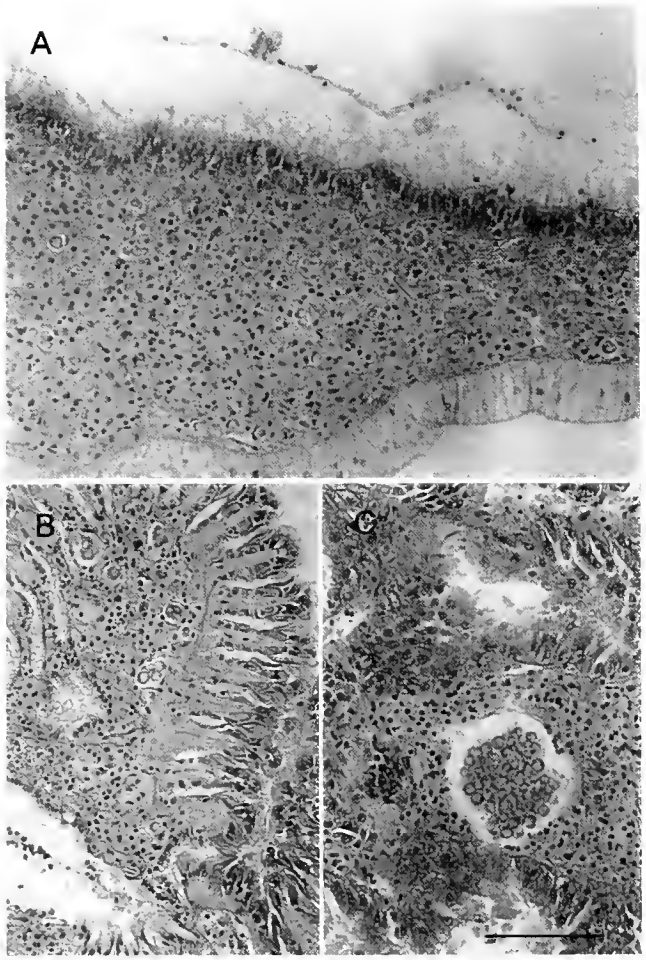

Figure 2. Mature trophozoites of *Perkinsus atlanticus* in Manila clam (*Ruditapes philippinarum*) tissues. This stage has a large eccentric vacuole without a vacuoplast, and a dark nucleus. (A) *Perkinsus atlanticus* located in the mantle edge. Note the strong hemocytic reaction associated with the infection. (B) Clam's gills heavily infected by *Perkinsus atlanticus*. In this case, the parasite cells are grouped in small clumps (fewer than five individuals per clump). Most of the groups are surrounded by a light halo. (C) Accumulation of *Perkinsus atlanticus* trophozoites in the tissue surrounding digestive tubules. The halo around the large parasite clump is surrounded by numerous hemocytes. Bar = 100 µm.

and stage. Palintomic cells, named tomonts by Perkins (1996), were also frequently detected in the clam tissues (Fig. 7). They were larger than mature trophozoites, and were not usually found clustered. Before the onset of palintomy, mature trophozoites lost the vacuole, which mixed with the cytoplasm (Fig. 7A). This prepalintomic stage was similar in size to the tomont, and showed a dense undifferentiated aspect.

Once the palintomy started, two- and four-daughter-cell tomonts were clearly identified in the clam tissues (Fig. 7B, Fig. 7C, Fig. 7D). When the number of daughter cells was too high, the tomont had a granulated aspect with several dark nuclei (Fig. 7E). Sometimes, the vacuole did not disappear from mature trophozoites before the palintomy and during palintomy underwent divisions to give the daughter cells inside the tomont (Fig. 7B, Fig. 7C, Fig. 7F). Occasionally, small immature trophozoites without vacuole were observed. Their cytoplasm was undifferentiated but nucleus and nucleolus were well defined (Fig. 5B, Fig. 7G, white

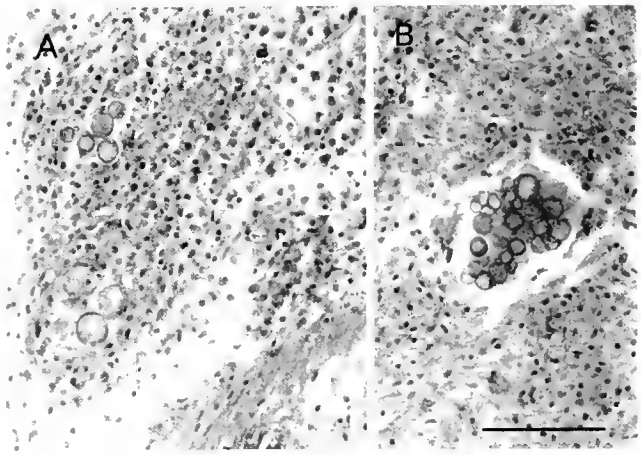

Figure 3. Mature trophozoites of *Perkinsus atlanticus* in *Ruditapes pullastra* tissues. Note the similarity of these parasite cells with those present in Manila and carpet-shell clam tissues. The trophozoites have a large eccentric vacuole and a dark nucleus, and are associated with strong hemocyte infiltration. They can appear individually (A) or in large clumps (B). In the latter case, a light halo usually surrounds the grouped parasite cells. Bar = 50 µm.

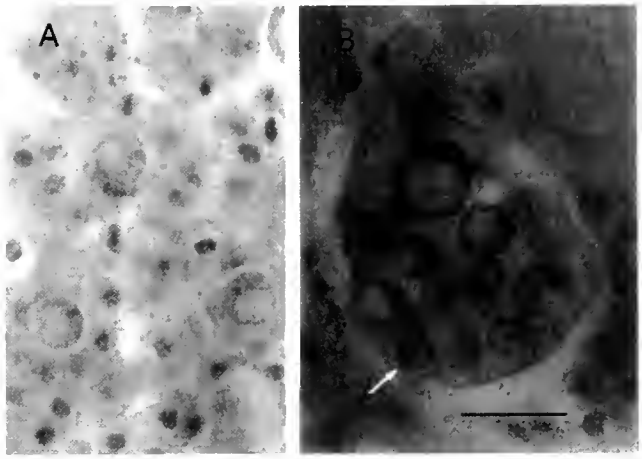

Figure 5. Mature *Perkinsus atlanticus* trophozoites internalized by carpet-shell clam (*Ruditapes decussatus*) hemocytes, probably granulocytes. (A) Hemocytes containing one *P. atlanticus* cells and (B) containing to ten *P. atlanticus* cells. Bar = 25 µm.

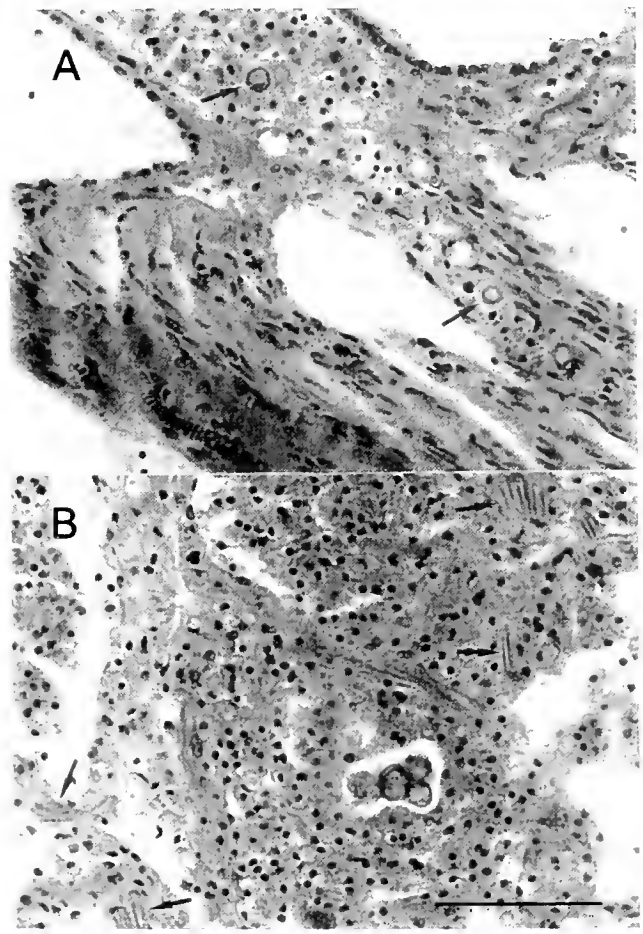

Figure 4. Mature trophozoites of *Perkinsus atlanticus* in carpet-shell clam (*Ruditapes decussatus*) tissues. The morphology of this life-cycle stage, with a large eccentric vacuole and a dark nucleus, is similar to that of the *Perkinsus atlanticus* present in Manila clams and *R. pullastra*. (A) *Perkinsus atlanticus* (arrows) in the gill epithelium. Note the strong hemocytic reaction and the disorganization of the tissues. (B) *Perkinsus atlanticus* in the muscle tissue. The clump, constituted by four mature trophozoites, is surrounded by a light halo. Among the numerous hemocytes, pieces of muscle tissue are seen (arrows). Bar = 50 µm.

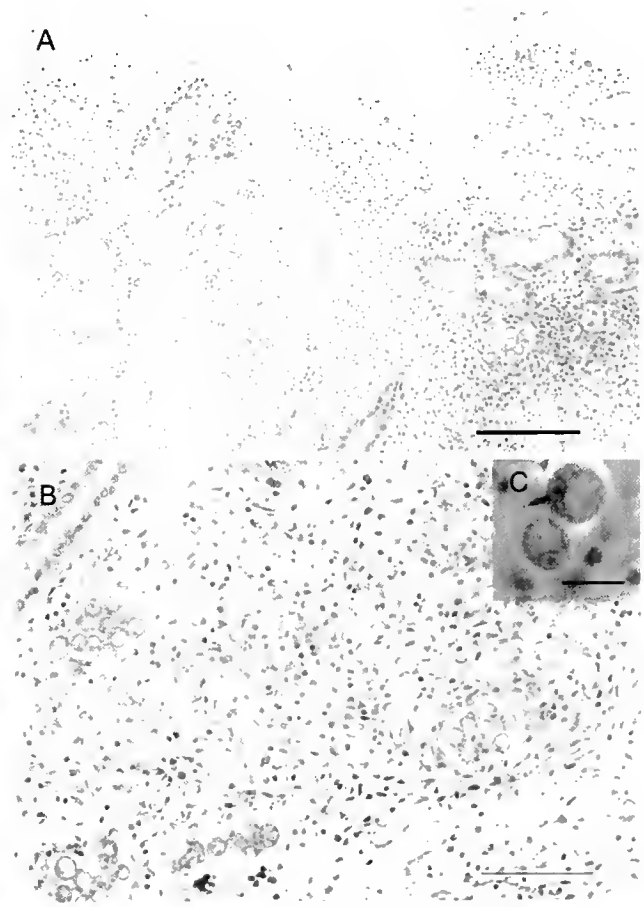

Figure 6. General view of carpet-shell clam (*Ruditapes decussatus*) tissues heavily infected with *Perkinsus atlanticus*. Note the strong hemocytic infiltration (A) and the light halos surrounding the parasite clumps (B). The most prevalent stage is the mature trophozoite (detail in C), with an eccentric vacuole and a nucleus containing a dark nucleolus. Immature trophozoites are also present in the clam tissue (B), with an undifferentiated cytoplasm and no vacuole. Several dark lipid droplets are present in their cytoplasm. The immature trophozoites are grouped and surrounded by a light halo. Bar = 100 µm (A), 50 µm (B), and 15 µm (C).

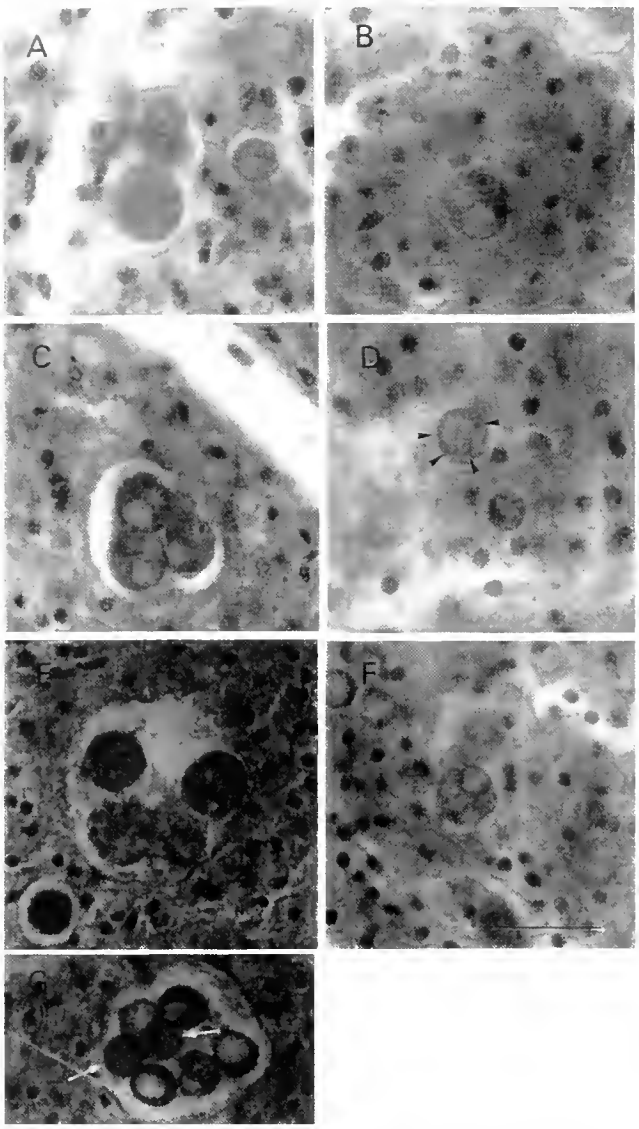

Figure 7. Palintomy of *Perkinsus atlanticus* in the carpet-shell clam (*Ruditapes decussatus*) tissues. (A) Mature trophozoites after loosing the vacuole by its mixing with the cytoplasm. The nucleus is distinguishable as a dark spot. Two- (B, C) and four- (D) cell daughter tomonts. Nuclei of the four- cell tomont are pointed with arrowheads. (E) Tomont in advanced palintomy, with a high number of daughter cells whose nuclei are observed as dark spots. (B, C, F) Palintomy of trophozoites whose vacuoles were not lost prior to palintomy. The vacuole is successively divided with the cytokinesis (B, C), until the tomont acquires a multivacuolated aspect (F). (G) Small immature trophozoites without vacuole, with undifferentiated cytoplasm but nucleus and nucleolus well defined (white arrows). Bar = 25 μm.

arrows). Generally, the diameter of the protozoan cells infecting the host tissues varied from 3–15 μm.

Frequently, a light halo, which resembled an empty capsule, surrounded the clumps of parasite cells (Fig. 2C, Fig. 4B, Fig. 6). A high number of hemocytes were grouped around these capsules. The presence of every life cycle stage of *Perkinsus atlanticus* was associated with a strong host hemocytic reaction (Fig. 2, Fig. 3, Fig. 4, Fig. 6). When the infection was heavy and the *P. atlanticus* cells were distributed in all host tissues, they looked disorganized with massive hemocyte infiltration.

DISCUSSION

In general, the morphology and distribution of *Perkinsus atlanticus* in the tissues of the three clam species from Galicia were similar to those reported before for *Perkinsus* infecting different host species around the world (Lester & Davis 1981, Azevedo 1989, Montes et al. 1995a, Sagristà et al. 1995, Perkins 1996, Blackbourn et al. 1998, Hamaguchi et al. 1998, McLaughlin & Faisal 1998a, Bower et al. 1999, Maeno et al 1999). Cultured *P. marinus* and *Perkinsus* sp. cells have been reported to develop vacuolated immature trophozoites inside the tomont (Perkins 1996, McLaughlin & Faisal 1998b), as we found for *P. atlanticus* in the clam's tissues. On the other hand, and in contrast to *P. marinus* (Perkins 1996), no vacuoplast was observed inside the *P. atlanticus* vacuole. *P. olseni* also lacks this inclusion (Lester & Davis 1981). The presence of a *Perkinsus* species in *R. pullastra* has only been reported in the South Spanish Atlantic coast (Navas et al. 1992). Therefore, this is the first time that *Perkinsus* is described in such economically valuable clam species in Galicia.

Recently, a new protozoan parasite morphologically similar to *Perkinsus* has been described in carpet shell clam from Galicia (Figueras et al. 2000). Moreover, this new species, named *Pseudoperkinsus tapetis*, develops hypnospores in RFTM indistinguishable from *Perkinsus* hypnospores. In spite of the coexistence and visible similarity of the two organisms (Ordás & Figueras 1998, Novoa et al. 2001), the parasitic cells observed and described in this paper should be mainly *Perkinsus* since its prevalence is much higher than that of *P. tapetis* (Novoa et al. 2001).

The initial response of the host to the *P. marinus* infection is the hemocytosis and the migration of hemocytes to the infection site (Lauckner 1983). This could be the origin of the strong hemocytic infiltration associated with the presence of *P. atlanticus* in the clam tissues. When the *P. atlanticus* infection rate is very high, the accumulation of hemocytes can be macroscopically observed as white cysts as previously reported by Lauckner (1983), Azevedo (1989), and Sagristá et al. (1995).

The encapsulation of the parasite is associated with the secretion of a "specific" protein by the granulocytes that had migrated to the infection place and surround the parasite cells (Montes et al. 1995b, Montes et al. 1996, Montes et al. 1997). In this study, the capsules that surrounded the *P. atlanticus* clumps seemed empty. This could be due to the histological processing that might have extracted the capsule material. However, *P. marinus* releases proteases when cultured in vitro (La Peyre et al. 1995) that alter several host defense parametres (Garreis et al. 1996) and degrade certain proteins of the oyster hemolymph (Oliver et al. 1999). Therefore, it could also be possible that *P. atlanticus* secretes similar proteases in vivo, these being responsible for the digestion of the capsule material and interference with the host defense response.

The oyster tissues with higher prevalence of *Perkinsus marinus* are the gills and the digestive gland (Lauckner 1983, Oliver et al. 1998). The hypothesized strategy of *P. marinus* for entering into the host (through feeding) would explain this distribution (Lauckner 1983, Andrews 1988). In the carpet-shell clam, the connective tissue of the organs shows the highest *Perkinsus* infection degree (Chagot et al. 1987). These results agree with our observations of the clam tissues infected with *P. atlanticus*.

Cheng (1988) defined *Perkinsus marinus* as an extracellular parasite, although it can be phagocytized by the hemocytes and be destroyed intracellularly. In contrast, Perkins (1996) considers

that, although the parasite cells can be found free in the host tissues, they are most commonly located in the phagosomes of the hemocytes. In any case, we have frequently observed one to ten *P. atlanticus* cells inside a clam hemocyte. If the hemocyte is not able to destroy the internalized *Perkinsus* cells, the parasite could grow inside the blood cell until finally destroying it, thus diminishing the host cellular defence factors. However, a relationship between the hemocyte lysis and the capsule formation around the *Perkinsus* cells has been reported by Montes et al. (1995b, 1996, 1997), constituting a host reaction to the hemocyte destruction by the parasite proliferation. The morphology of the host hemocytes that have internalized the *P. atlanticus* cells corresponded to granular hemocytes. In fact, it is well known the higher phagocytic activity of the granulocytes compared to the hyalinocytes in bivalve molluscs (Fisher 1986, Feng 1988).

ABSTRACT The protistan parasite *Perkinsus marinus* has been responsible for high mortality of eastern oysters, *Crassostrea virginica*, along the Atlantic and Gulf Coast of the United States. It also causes sublethal effects, although an impact on reproduction has heretofore been difficult to demonstrate. We examined the effect of *P. marinus* infection on growth, reproduction (as measured by relative gonadal size, and the proportional representation of gametogenic tissue and gametes in the gonad), and condition index of eastern oysters. Oysters of known age and genetic history were exposed to *P. marinus* infection and sampled at 2–4 week intervals over an 11-month period during the 1990–1991 epizootic in Delaware Bay. During this time, 50 to 100% of the oysters had detectable infections and nearly 55% died. Shell growth rates were inhibited as infections intensified during initial exposure in autumn 1990, but resumed in the spring and remained high, even after infection became heavy. The effect on reproduction varied with the stage of the gametogenic cycle. The relative gonadal size and the proportion of gametogenic tissue in the gonad, as well as the condition index, were most strongly depressed during the spring gametogenic period; however, there was no significant effect of parasite burden when the oysters were reproductively mature and ready to spawn. Data suggested that infected oysters, recovered, produced gametes, and spawned in early summer. Other studies have found inconsistent evidence of sublethal deleterious effects of *P. marinus* on reproduction. By sampling throughout the year and employing oysters of known genetic background, of the same age, reared in a common environment, and for which the timing of initial infection was known, we were able to show that *P. marinus* does have significant negative effects on oyster reproduction, measurable primarily during gametogenesis, rather than at spawning.

KEY WORDS: *Perkinsus marinus*, oysters, reproductive stage, reproduction, parasite effects, condition index

INTRODUCTION

In Delaware Bay, two major protozoan parasites, *Perkinsus marinus* (Mackin, Owen, Collier 1950, Levine 1978) and *Haplosporidium nelsoni* (Haskin, Stauber, Mackin 1966) infect oysters, *Crassostrea virginica* (Gmelin 1791) (Ford & Haskin 1982, Ford 1996). These parasites cause severe physiological disruption in the host oysters, often leading to death (Ray et al. 1953, Ford & Figueras 1988, Choi et al. 1989, Ford & Tripp 1996, Paynter 1996). They have been recognized as a cause of oyster mortality along the east coast of the United States for at least 40 years (Ford & Tripp 1996). While *H. nelsoni* has been prevalent in Delaware Bay since the late 1950s, *P. marinus* did not become epizootic in until the late summer of 1990 (Ford 1996). Before that, only sporadic and very low levels of this parasite were found in the Bay. The sudden upsurge of *P. marinus* infections is probably due to a history of introductions of infected oysters into Delaware Bay and an environmental warming trend that allowed the parasite to become epizootic (Ford 1996, Cook et al. 1998).

Decreased reproduction is one common effect of parasites on their hosts (Thompson 1983, Barber et al. 1988, Forbes 1993, Choi et al. 1994, Ford & Tripp 1996). While infection by *H. nelsoni* has been shown to have a significant sublethal effect on reproduction (Barber et al. 1988), similar evidence for *P. marinus* has not been definitive (Choi et al. 1994, Kennedy et al. 1995, Paynter 1996). Kennedy et al. (1995) were able to detect some deleterious effects of *P. marinus* infection on gametogenic characteristics, but not in a consistently predictable pattern. Barber (1996) found that *C. virginica* exposed to infections by both *H. nelsoni* and *P. marinus* in Virginia showed little gametogenesis at all; however, the relationship between level of parasitism and gonadal stage in individual oysters was not reported. To explain variable effects of infection, there has been speculation that oysters can divert energy from growth to reproduction when infected with *P. marinus* (Choi et al. 1994, Kennedy et al. 1995, and Hofmann et al. 1995). Both reproduction and energy storage in bivalves have distinct seasonal cycles. *Perkinsus marinus* infection and subsequent disease development also have seasonal patterns influenced by environmental temperature and salinity (Andrews 1988, Ford & Tripp 1996, Kennedy 1996). To properly assess the effects of parasites on reproduction and condition of their hosts under these conditions, it is necessary to sample at all stages of both the infection and reproductive cycles. In this study we measured the effects of *P. marinus* on the eastern oyster by examining individuals of known genetic background and age, reared in a common environment. We followed the effects of *P. marinus* from the first signs of disease in early August of 1990 until the majority of the oysters had heavy infections at the end of June of 1991. Our goal was to quantify the effect of parasitism on the oysters at different stages of the reproductive cycle. Oysters are a commercially important species and a significant component of the estuarine ecosystem. Therefore, a direct quantification of the impact of the parasite on host reproduction, and the timing of this impact, will provide useful information for management decisions (Powell et al. 1994, Kennedy 1996, Krantz & Jordan 1996, Powell et al. 1997).

MATERIAL AND METHODS

Test Oysters

Strains of *C. virginica* have been maintained in a common environment (lower Delaware Bay) for multiple generations since the 1960s, as part of a selective breeding project for resistance to

*This paper is dedicated to F. James Rohlf on the occasion of his 65th birthday.

MSX disease, caused by *H. nelsoni* (Haskin & Ford 1979, Ford & Haskin 1987). In 1988, oysters from Long Island Sound origin (Rutgers LA strain) and Delaware Bay origin oysters (Rutgers XF strain) were spawned to produce pure lines and reciprocal crosses. These 1988 year-class animals were seventh generation representatives of the inbred MSX disease-resistant strains produced in the Haskin Shellfish Research Laboratory breeding program. All were produced and reared under identical conditions (see Dittman et al. 1998).

Sampling

We determined reproductive state, condition index, and parasite infection intensities by sampling forty oysters at 2-week (spring, summer, and fall) to 4-week (winter) intervals from August 1990 to July 1991. Equal numbers (N = 10) of offspring from each pure line and their reciprocal crosses were sampled. Similar size distributions (as measured by maximum shell dimension) were sampled on each collection date to minimize the effect of absolute size on the estimates of reproductive measurements and condition index (Galtsoff 1964, Rainer & Mann 1992). Shell sizes of 400 haphazardly chosen individuals were measured every three weeks to monitor shell growth. Dead oysters were counted and removed at regular intervals and cumulative mortality was computed over the study period.

Sample Processing

The shell height (longest dimension from umbo to growing edge) of each oyster was measured with a calipers to the nearest 1 mm. Whole live weight, (wet shell and soft body mass) was measured to the nearest 0.1 g. The shells were opened and the body was removed. Soft body mass was measured to the nearest 0.1 g. Air-dried valves were weighed to the nearest 0.1 g. The rectum was removed and cultured for *P. marinus* in Ray's fluid thioglycollate medium (RFTM, Ray 1966). Oysters were individually tagged and fixed in Davidson's solution for 24 hours, and then placed in 70% ethanol for storage until histological analysis was conducted.

To eliminate possible confounding effects of MSX disease on the analysis, all oysters were examined for *H. nelsoni* infections by standard tissue section histology. The oysters were processed using the procedure of Barber et al. (1988) for combined condition index measurement and histology. In this procedure, the whole fixed tissue was weighed and a standard 5-mm-transverse section through the gills and visceral mass between the palps and the adductor muscle was removed. The section and the remaining tissues were then weighed separately. The remaining tissue was dried for the calculation of individual condition index. The section was dehydrated through an alcohol series, cleared in xylene, embedded in paraffin, and sectioned at 5 μm. Tissue sections were stained with iron hematoxylin, acid fuchsin, and aniline blue. The slides were used for the measurement of reproductive condition, as well as to determine the presence and intensity of *H. nelsoni*.

Reproductive Measures

The Gonadal Index (GI), which is the proportion of the cross-sectional visceral mass area occupied by the gonad, is a useful estimate of fecundity in oysters provided individuals with similar environmental histories are compared (Barber et al. 1988, Heffernan & Walker 1989, Morales-Alamo & Mann 1989). In our study, the GI was estimated by image analysis. In addition, the proportion of the gonad occupied by all gametogenic tissue (gamete producing follicle tissue and gametes) and by gametes alone was estimated using point-count stereology on two randomly chosen (×400) microscope fields of each oyster (Elias et al. 1971).

Condition Index

The Condition Index (CI) is a standard measure used in shellfish growth and reproductive-cycle analyses (Widdows 1985). It is an indication of long-term changes in individual nutrient status and is a useful measure of the metabolic state of bivalves, including that produced by stress (Rainer & Mann 1992). It is often used to demonstrate seasonal physiological changes in natural populations (Lawrence & Scott 1982). We determined CI as the proportion of the internal shell volume occupied by dried soft tissue:

$$CI = (\text{dry body mass (g)} / \text{internal shell volume (mm}^3)) \times 100.$$

Internal shell volume was estimated as the difference between whole live weight and valve weight (Lawrence & Scott 1982). Total dry body mass was adjusted to account for the section removed for histology by assuming that the wet mass of the section had the same proportion of water as the rest of the tissue.

Infection by Parasites

Rectal tissues incubated in RFTM were stained with Lugol's Iodine, spread on a slide, and the level of P. *marinus* infection was rated on the Ray/Mackin scale of 0–5 using a compound microscope (Ray 1954, Mackin 1962). A 0 rating indicated that no were parasites detected, while a rating of 5 indicated that the oyster tissues were almost completely replaced by parasites. There is an exponential relationship between the Ray/Mackin scale and parasite abundance in the tissue (Choi et al. 1989), so when single or few parasites were found in the tissue samples, we gave a rating of 0.5 rather than 1 to allow us to distinguish, for the purpose of testing for parasite effects, between a very low level of detected infection and the relatively higher rating of 1. For the sake of simplicity, we will term oysters in category 0 "uninfected", although we recognize that they have a high probability of being parasitized (Bushek et al. 1994). Sample infection levels are reported as prevalence and the weighted prevalence (WP), which is the mean of all infection intensities including those rated 0.

Tissue slides of all oysters were examined for the presence and intensity of *H. nelsoni* (Ford & Haskin 1982). Oysters with advanced or systemic *H. nelsoni* infections were eliminated from analyses so as not to confound measurement of the effect of *P. marinus* (Ford & Figueras 1988, Ford et al. 1990).

Statistical Analysis

To facilitate analysis, we grouped the oyster samples into six periods according to published descriptions of the seasonal reproductive cycle (Loosanoff 1942, Ford & Figueras 1988, Thompson et al. 1996). The reproductive patterns of the oysters in this study fit the published descriptions. The first period was August and September of 1990, the end of spawning for that summer, when the animals were reabsorbing gametes. The second period was October to mid-December, when the oysters were reproductively inactive. The third period encompassed early gametogenesis, from January to early April 1991. The fourth period was from mid-April through early May, when the oysters were undergoing rapid gametogenesis. The fifth period was mid-May to early June, when the oysters were fully ripe and beginning to spawn. The last period

was from the middle to the end of June 1991, when the oysters were in late spawning.

When the samples within infection classes were <5, they were pooled for the analysis. In addition to the oysters eliminated from analysis because of *H. nelsoni* infections, two animals with trematode, *Buccephalus* sp., infections were excluded, because this parasite often castrates its hosts (Ford & Tripp 1996). A total of 679 oysters were analyzed.

Two-way ANOVAs were performed to test the effects of sampling date and parasite burdens on reproductive measures and condition index (Sokal & Rohlf 1981). Preliminary tests indicated no significant effect of strain so that all 4 groups were pooled for further analysis. A separate ANOVA was performed for each of the six reproductive periods. Multiple comparisons among infection-category means during each reproductive period were made using the Tukey-Kramer method (Sokal & Rohlf 1981, Gagnon et al. 1990). Correlation analysis was performed to determine the relationship between shell size and *P. marinus* intensity during infection peak in the autumn of 1990 and the early spring of 1991. Differences were considered significant at $p = 0.05$.

RESULTS

Perkinsus marinus infections were first detected in the experimental oysters in mid August of 1990, at which time prevalence was 18%. All but one infection were category 0.5; one oyster had a level 1 infection. Prevalence and intensity increased through fall and early winter, then declined gradually over the winter and spring, reaching a low in early May 1991 (Fig. 1, Table 1). Both measures then increased dramatically from mid May to early June 1991. Mortality rose to 30% between the beginning of August and early November 1990, ceased over the winter and early spring, and resumed in mid May 1991 (Fig. 2). Between mid May and the end of June, when the final sample was collected, 30% of the remaining oysters died, raising the total cumulative mortality to about 55%. The high death rate continued after the study ended so that by September 1991, an estimated 97% of the oysters had died.

Despite the high disease pressure, the mean size of oysters increased over the study period (Fig. 3). A lag in the rate of

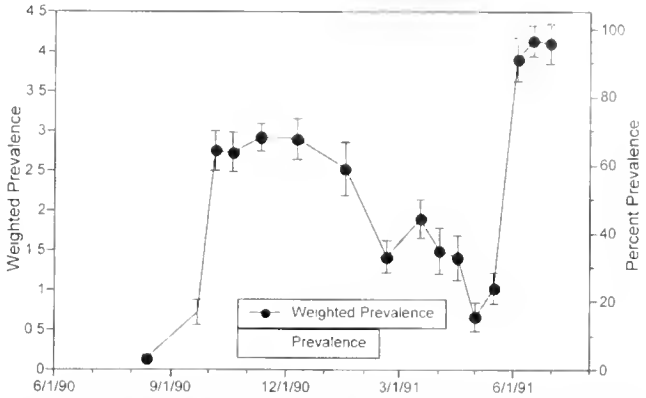

Figure 1. Seasonal pattern of *Perkinsus marinus* prevalence (percent) and weighted prevalence (mean ± se) during the study period. Each data point represents 40 oysters.

increase occurred from mid October to mid November 1990, coincident with the initial development of *P. marinus* infections, and a decrease in size was measured in late winter that may have been a combination of no growth and chipping of the shell edge. Rapid shell growth resumed in early April and continued through the early summer of 1991; even after infection intensities had become heavy (Fig. 1, Fig. 3). There was a marginally nonsignificant association between shell size and WP during the autumn, 1990, infection peak ($p = 0.077$, $r^2 = 0.011$); the correlation for the June 1991 peak was significant, although weak ($p = 0.015$, $r^2 = 0.054$). At both times, however, the correlation coefficient was positive, indicating that the larger oysters tended to be the more heavily infected.

The GI decreased from a peak of 0.55 to about 0.15 as spawning progressed during the summer of 1990, before the *P. marinus* epizootic began. It began to rise again in mid April 1991 and peaked in mid to late May at 0.40, then declined through June, when our sampling ended (Fig. 4). Overall, we found a strong seasonal variation in the effects of *P. marinus* infection on the reproduction and condition of oysters (Table 2). During the gamete resorption phase of late summer 1990, most oysters were not de-

TABLE 1.

Prevalence and intensity of *Perkinsus marinus* infection in oysters sampled from lower Delaware Bay from August 1990 to late June 1991. Prevalence is the percentage of oysters infected in a given period. Intensity is the percentage and number of oysters in a period that had a given intensity of infection (Ray/Mackin ratings).

Stage of the Reproductive Cycle (Sample Dates)	Total N	% Infected	No Infection (0) % (N)	Light Infection (0.5 & 1) % (N)	Moderate Infection (2 & 3) % (N)	Heavy Infection (4) % (N)	Very Heavy Infection (5) % (N)

tectably infected or had only light infections (Table 1). Nevertheless, there was a significant overall effect of infection on the GI, caused by the few oysters with moderate to heavy infections. The average GI of these individuals was half that of the uninfected oysters (Fig. 5). We found no significant effects on the other reproductive measures or on the condition index (Table 2, Fig. 6, Fig. 7, Fig. 8).

During the fall–early-winter period there was no obvious reproductive activity as judged by the absence of gametes and the very low quantity of gametogenic tissue. Nevertheless, we measured a significant effect of parasite burden on both GI and CI (Table 2). Again, it was the worst infected oysters that were affected. The average GI of heavily infected oysters (Ray/Mackin rating = 5) was two–thirds that of uninfected oysters and the CI was three-quarters (Fig. 6). There was no significant effect on the proportion of gametogenic tissue (Table 2, Fig. 7).

In both the gamete-resorption and the reproductive–inactivity periods, 2-way ANOVAs showed a significant effect of sample date, indicating that the measures of reproduction and condition changed over time within these periods. There were no significant interactions of parasite burdens and sample dates in any of the analyses, however, indicating that the relative pattern of the effects of these two factors did not change.

During the winter period of early gametogenesis there was a significant effect of parasite burden on all measures of reproduction and the CI (Table 2, Fig. 5, Fig. 6, Fig. 8). The average GI in heavily infected oysters was half that of uninfected oysters, but there was a trend toward smaller indices in oysters beginning with category 3–4 infections (Fig. 5). Similarly, the average proportion of gametogenic tissue and gametes was also about half that of uninfected oysters (Fig. 7, Fig. 8), with a suggestion that gamete production was impaired in oysters with relatively light infections (Fig. 7). Even though average parasite burdens declined, as is typical during the spring (Fig. 1), reproductive activity during the period of late gametogenesis was severely impaired by *P. marinus*. All measures of reproduction, as well as the CI, were affected (Table 2). The clearest impact was on the GI, which was significantly depressed at all infection levels (Fig. 5). The gonads of oysters with category 2–5 infections occupied, on average, only one-third the proportional area as those of uninfected or lightly infected individuals. The average proportion of gametogenic tissue and gametes in oysters with categories 4 and 5 infections, was only a quarter of that in uninfected oysters (Figs. 7 and 8). The CI of the most heavily infected oysters was two-thirds that of uninfected oysters (Fig. 6).

Finally, during both the early spawning period of late May to early June and the later spawning period of mid-June to late June there were no detectable effects of parasite burdens on any of the reproductive indices or on CI (Table 2, Fig. 5, Fig. 6, Fig. 7, Fig. 8). There were marginally nonsignificant trends toward less gametogenic tissue (Table 2, $p = 0.058$) and fewer gametes (Table 2, $p = 0.081$) during the later spawning period, but statistical power was lost due to small sample sizes in the uninfected and lightly infected categories (Fig. 7, Fig. 8).

DISCUSSION

One of the most common sublethal effects of parasites on their host is a reduction in growth and reproduction (Thompson 1983, Price et al. 1986, Ford & Figueras 1988, Forbes 1993, Ford & Tripp 1996). Although an inhibitory effect of *P. marinus* on oyster growth has been reported (Menzel & Hopkins 1955, Paynter & Burreson 1991), the consistent quantification of an impact on reproduction has been elusive to date (Choi et al. 1994, Kennedy et al. 1995, Paynter 1996). We found clear evidence that *P. marinus* infection had a significantly negative effect on relative gonadal size, and on the proportions of gametogenic tissue and gametes in the gonad. Detection of an effect depended on when during the disease and reproductive cycles the sample was taken, the type of

measurement made, and the parasite burdens of the oysters examined. The effect was most pronounced during the gametogenic phases of the reproductive cycle, but an effect on relative gonadal size could also be detected during the gamete resorption and overwinter inactivity periods. Interestingly, by the time oysters were reproductively mature and ready to spawn, we were no longer able to measure an effect of the parasite, although later in the spawning period there was again a trend (marginally nonsignificant) of decreasing proportion of gametes with increasing *P. marinus* burdens.

The effect of *P. marinus* increased with increasing infection intensity and was generally statistically significant only in oysters with heavy infections (Ray/Mackin rating of 4 or 5). During gametogenesis, heavy infections reduced the relative gonadal size to an average one-third to one-half that of uninfected or lightly infected oysters, and in some individuals with advanced infections, the gonad could not be detected at all. The other major disease agent of eastern oysters, *H. nelsoni*, impairs reproduction to a similar extent. Barber et al. (1988) reported that the Gonadal Index (GI) of oysters heavily infected with *H. nelsoni* averaged 50% or less that of uninfected animals and in several samples the gonadal area could not be measured.

The reduction in GI, by itself, reflected a potentially serious impact of *P. marinus* infection; however, the additional measures that we obtained in this study, CI and the proportion of the gonad occupied by gametes, indicate that the negative effect of *P. marinus* infection was considerably more severe than the GI alone would indicate. For example, the most extreme inhibition was measured during the period of rapid gametogenesis in the spring, when oysters having infections rated 4 or 5 had one-third the GI, with only one quarter of the gonadal area being filled with gametes or gametogenic tissue. Thus, the two-dimensional cross-sectional body area measured, contained fewer than 10% as many gametes as did the cross-sectional area measured in uninfected individuals. Further, the CI (directly correlated with cross-sectional body area, $p < 0.0001$) indicated that heavily infected oysters had only two thirds as much soft tissue as uninfected animals. Thus, the cross-sectional area, on which the proportional measures are based, was itself considerably diminished with infection, further reducing the absolute number of gametes produced.

The negative effect of *P. marinus* infection on reproduction and condition was clear during the period of gametogenesis, but it was absent or inconsistent for the same measurements made during other phases of the reproductive cycle. To understand the variable effects of the parasite at different seasons, it is necessary to consider the metabolic changes experienced by both the host and the parasite, and how they may interact, over the course of a year.

As oysters were ending the reproductive season in the late summer of 1990, all measures of reproduction were decreasing and *P. marinus* infections were beginning to intensify. The significant ANOVA effect of parasitism at this period was produced by the few infections that reached the moderate to heavy stage (Table 1) and depressed the GI to about half that of oysters with lighter or no detectable infections. The same trend continued into the fall and early winter, as many more oysters became heavily infected and by which time the impact of parasitism was measurable in reduced CI. Even though gamete production was not occurring, the relative area occupied by gonadal follicles was diminished. Glycogen, which is being stored in the late summer and fall, and which is measured by CI, is stored in the cells surrounding each follicle. The relative "fullness" of the storage cells is likely to have affected the measurement of gonadal size. That is, the GI is likely to have been relatively large in animals with high glycogen (CI), because it would include expanded storage cells. Because the amount of gametogenic material produced is directly related to the quantity of glycogen stored before gametogenesis (Loosanoff 1965), the impact of *P. marinus* on reproduction may begin as early as the late summer and fall of the preceding year. Kennedy et al. (1995) also

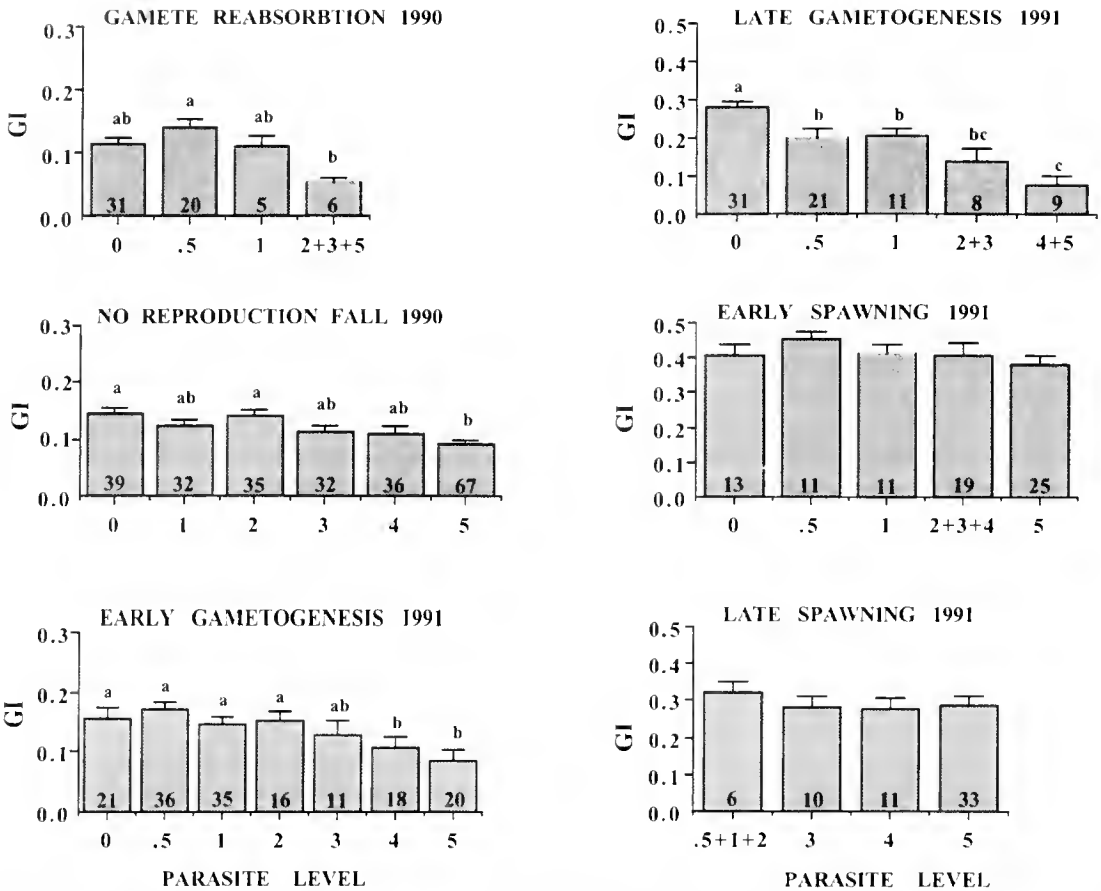

Figure 5. Mean (± se) gonadal index for oysters, plotted according to *Perkinsus marinus* infection category, during all 6 reproductive cycle periods. When there were small sample sizes, parasite levels were pooled as indicated. Letters above the columns indicate statistically significant differences ($p < 0.05$).

hypothesized that reproductive capacity would be impaired if oysters had been parasitized the previous year, but were unable to confirm it.

Probably the most surprising finding was the lack of measurable effect of *P. marinus* on the reproductive and condition indices at the time of maximum reproductive condition (mid-May through early June) when the mean GI was 0.4 or more, and 80% of the gonad was occupied by gametes in oysters of all infection levels, including those patently uninfected. Given the very serious effect that parasitism had had during the gametogenic period, just a few weeks earlier, this almost sudden lack of effect is puzzling. Death of heavily infected oysters was not responsible because spring mortality did not begin until after this peak condition had already been reached (Figs. 2 and 3). Further, both the early and late spawning periods, (from mid-May through the end of June) contained substantial numbers of oysters with advanced infections that showed no statistical effect of infection on gonadal indices. The data therefore indicate that the oysters showing a pronounced effect of parasitism during the gametogenesis were the same individuals that showed essentially no effect of parasitism several weeks later, when they were reproductively mature.

To help explain this phenomenon, it important to remember that the period in question is one of very rapid change. The spring phytoplankton bloom provides ample food (Ford 1986, Powell et al. 1997), oyster growth rates are rapid, as is gametogenesis. At the same time, infection intensities are diminishing within individual oysters. In our study, weighted prevalence reached a low point at the beginning of May 1991, coincident with the beginning of the most rapid increase in gonadal size. Only about 10% of the oysters had advanced (Ray/Mackin stage 4 and 5) infections at this time. Parasite burdens remained low through mid-May when the gonadal indices peaked. Consequently, during the period of most rapid gametogenesis and maturation, as measured by the doubling of the GI between mid-April and early June, *P. marinus* infection loads were not only very low, but had been decreasing for several months. Accordingly, it can be argued that this respite from the metabolic demands and physiological disruptions of the parasite, during a period of generally good food conditions, allowed the oysters to recover, build gonad, and spawn before parasite loads again reached the point at which they imposed a metabolic burden. Interestingly, Ford and Figueras (1988) reported a similar event in oysters infected with *H. nelsoni*. In that case, infection intensity diminished quickly in early June, much later than the gradual decrease recorded for *P. marinus*, but apparently in enough time for oysters to recover, produce gametes, and spawn later in the summer.

The apparent rapid recovery of sick oysters is remarkable, but reproduction did not entirely escape the effects of *P. marinus* infection during the spawning period. There was a trend towards a lower proportion of gametogenic tissues (nearly all gametes at this time) during the late spawning period, after infection levels had peaked. Also, *P. marinus* could also have been responsible for the

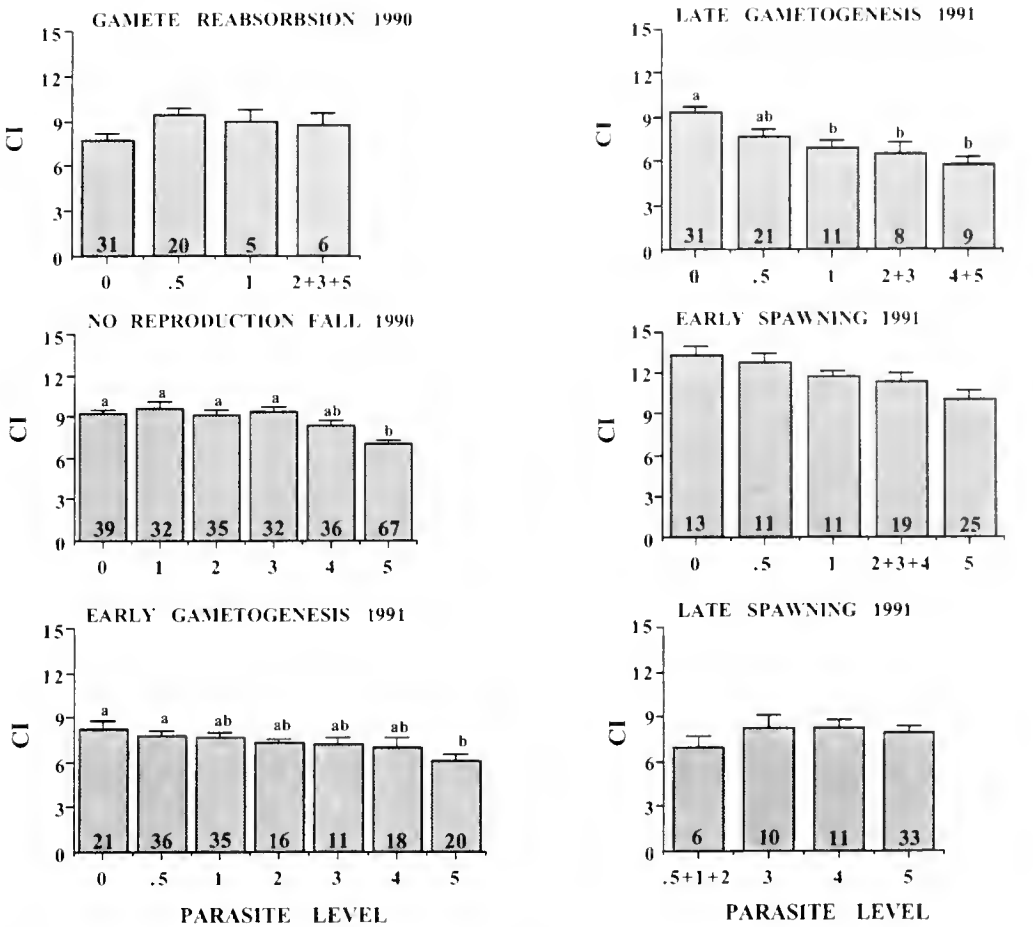

Figure 6. Mean (± se) present condition index for oysters, plotted according to *Perkinsus marinus* infection category, during all 6 reproductive cycle periods. When parasite levels were pooled due to small sample sizes it is indicated. Letters above the columns indicate statistically significant differences ($p < 0.05$).

overall lower GI in 1991 compared to 1990, before the epizootic, although year-to-year variability in food and other factors cannot be excluded. Since we did not measure egg size, there is a possibility that the infected oysters had smaller eggs, which would have diminished their chances of survival during the larval stage (see Gabbott 1983). Previous studies, however, found no reduction in egg size associated with either *P. marinus* or *H. nelsoni* infection (Barber et al. 1988, Kennedy et al. 1995).

We also found significant negative effects of *P. marinus* on oyster Condition Index (CI), consistent with previous research (Ray et al. 1953, Mackin 1962, Paynter & Burreson 1991), but not at all seasons. The effect was measurable beginning in autumn, as oysters stored glycogen, and was observed throughout the spring period during which time gametogenesis was progressing. It was absent, however, throughout the spawning period, probably for the same reason that there was no effect on the GI at this time.

These results fit in well with recent ideas and models of oyster populations that describe how the interaction *P. marinus* and the oysters may vary seasonally (Hofmann et al. 1992, Powell et al. 1994, and Hofmann et al. 1995). Oyster growth and allocation to reproduction are a balance between food supply and competing energy requirements (Hofmann et al. 1992, Thompson et al. 1996). Our results suggest that the metabolic demands of *P. marinus* (Choi et al. 1994) may begin in the fall, as nutrient reserves are being stored, and persist into the spring. As noted by others, the gametogenic period is stressful for many bivalves as in many cases, especially in more northern populations, as they are relying on stored food (Loosanoff 1942, Bayne & Newell 1983, Thompson et al. 1996). Our data are consistent with this view. The clear association between *P. marinus* and impaired gametogenesis during early spring suggests that oysters were relying on reserves stored in the autumn, which had been diminished in proportion to infection level, to begin gametogenesis. The ability of infected oysters to develop mature gonads later in the spring may reflect the direct conversion of food, rather than stored energy, into gametes. It is relevant that Newell et al. (1994) found little or no effect of *P. marinus* on feeding rates or assimilation efficiency indicating that infected oysters would be as able as uninfected individuals to obtain and assimilate the nutrients present in spring blooms.

Our data showing little or no effect of *P. marinus* at the time of maximum reproductive condition and during spawning is at variance with those of Kennedy et al. (1995). These authors followed two oyster populations in upper Chesapeake Bay and found the only measurable impact of *P. marinus* to be at spawning, when we found none. The Chesapeake Bay relationship was true at one site only, however. No effect of parasitism was found, at any time, at the second location. Consequently, site-specific factors are likely to have a large influence on the relationship between parasitism, reproduction, and somatic growth and these factors are probably the ones influencing the acquisition of energy. For instance, math-

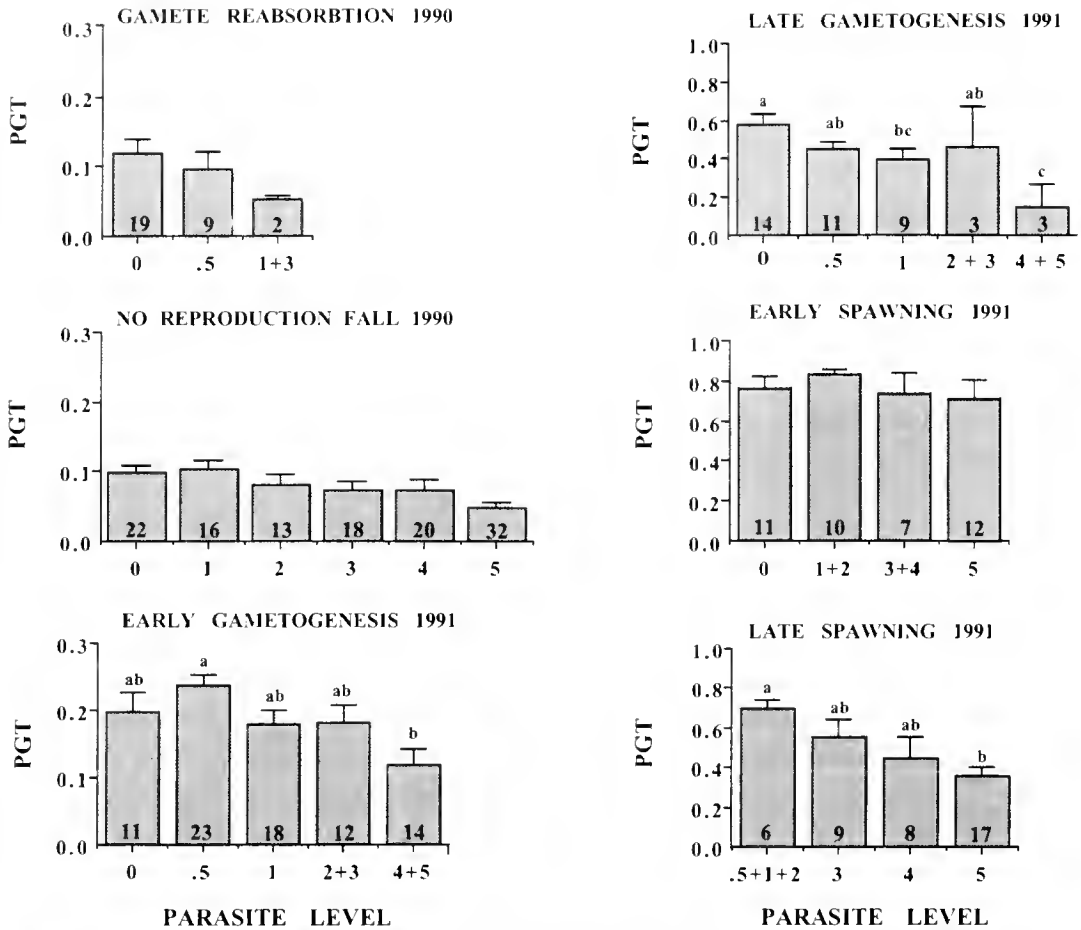

Figure 7. Mean (± se) percent gametogenic tissue for oysters, plotted according to *Perkinsus marinus* infection category, during all 6 reproductive cycle periods. When parasite levels were pooled due to small sample sizes it is indicated. Letters above the columns indicate statistically significant differences ($p < 0.05$).

ematical modeling suggests that the timing and extent of phytoplankton blooms can play an important role in the outcome of oyster–parasite relationships (Powell et al. 1996, Ford et al. 1996) and these are likely to vary widely, even in the same estuary system (Powell et al. 1997). Temperature differences, which would affect the timing of infection and reproductive cycles, would also be critical.

Menzel and Hopkins (1955) were the first to recorded an impact of *P. marinus* infection on oyster growth. By following individually marked oysters, they documented a negative correlation between parasite burdens and shell growth. More recently, Paynter and Burreson (1991) reported that even very light infections in a population of oysters were sufficient to markedly slow the average growth rate. We, too, recorded a decrease in shell growth rate coincident with the onset and development of infections in the autumn. When growth resumed in the spring, infection intensities were apparently too low to affect shell deposition, but rapid growth continued even after parasite loads became high. This unexpected result did not occur because heavily infected oysters died, as they tended to be larger, not smaller, than lightly infected animals. Rather, it may be due to the abundant food supply at the Cape Shore test site, which has always been an excellent location for oyster growth (Dittman et al. 1998). High phytoplankton levels may have provided sufficient nutrients to fuel gamete production and somatic growth, as well as parasite growth. Whether "recovery" would have occurred under less favorable conditions than we hypothesize is unknown. An interesting question is why has it been so hard to consistently quantify the sublethal effects of *P. marinus* infections on reproduction. Some studies suffered from low sample

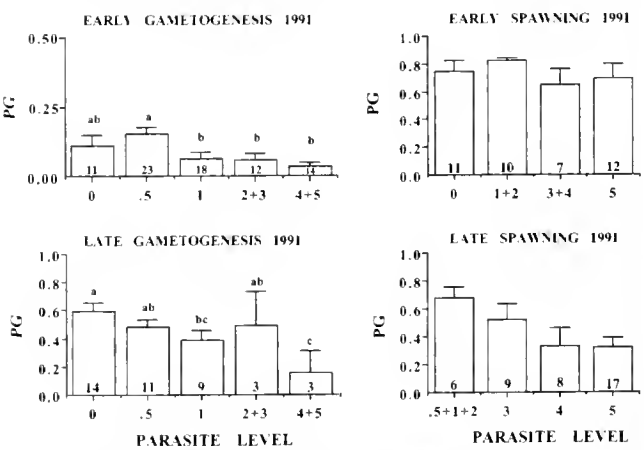

Figure 8. Mean (± se) percent gametes for oysters, plotted according to *Perkinsus marinus* infection category, during all 6 reproductive cycle periods. When parasite levels were pooled due to small sample sizes it is indicated. Letters above the columns indicate statistically significant differences.

sizes for the amount of reproductive and parasite level variation observed and there were scant data on the history of the oyster populations and their previous exposure to disease. Also, it is clear that for the most part, *P. marinus* intensities do not impair nutrient storage or reproduction until they become heavy (Ray/Mackin stages 4–5). Unless samples contain oysters with advanced infections, an effect of *P. marinus* on reproduction will be difficult to detect.

Our study has shown the need to consider the seasonal cycles of both protagonists in attempting to assess the metabolic effects of an endoparasite on its invertebrate host. Samples taken at a single season may fail to show an effect that is clear at another, nor will they provide the history of the populations needed to interpret any given sample result. For instance, the very drastic negative effect on reproduction predicted during the gametogenic phase did not materialize at the time of spawning because a period of diminishing parasite burdens coincided with gamete maturation. Our investigation was also helped because all oysters were of known age and genetic history, were reared in a common environment, and were exposed to the disease agent at the same time. All of these factors and an experiment that involved sampling throughout the host's reproductive cycle and the parasite's infection cycle allowed us to detect and interpret the effects of infection intensity on oyster reproduction more easily than would otherwise have been possible.

THE EFFECTS OF A REGULATORY GEAR RESTRICTION ON THE RECRUITING YEAR CLASS IN THE SEA SCALLOP, *PLACOPECTEN MAGELLANICUS* (GMELIN, 1791), FISHERY

JEFFREY C. BRUST, WILLIAM D. DUPAUL, AND JAMES E. KIRKLEY

Virginia Institute of Marine Science, School of Marine Science, College of William and Mary, P.O. Box 1346, Gloucester Point, Virginia 23062

ABSTRACT In 1994, Amendment 4 to the sea scallop (*Placopecten magellanicus*) fishery management plan was adopted, which restricted fishing effort by controlling vessel days at sea, crew size, and gear size. Dredge ring size was increased from 76.2 mm (3.0″) to 82.6 mm (3.25″) in March 1994, and again to 88.9 mm (3.5″) in January 1996 to increase the age of entry of scallops into the fishery. Between June 1994 and April 1995, four trips were taken on commercial scallop vessels in the western mid-Atlantic to determine harvest efficiency of 88.9-mm dredge rings relative to 82.6-mm dredge rings used in the fishery at the time. Our study focused on the abundant and nearly ubiquitous 3-year-old, 1990 year class. At the time, individuals in this year class were approaching the size (70 mm) of both full recruitment to the gear and recruitment into the fishery. Relative harvest efficiency of this year class ranged from 60% to 72% over the study period. The 88.9-mm rings were found to be 90% efficient when scallops had grown to a size of 100–105 mm. The 88.9-mm ring dredge would therefore delay full recruitment of the 1990 year class for almost 1 y relative to the 82.6-mm ring dredge. Analysis shows that this delay could increase yield-per-recruit by almost 10% and spawning stock biomass by 40% to 60%. Benefits of the gear modifications will only be fully realized when used in conjunction with other measures that reduce or stabilize fishing effort.

KEY WORDS: sea scallop, relative harvest efficiency, ring size, *Placopecten magellanicus*

INTRODUCTION

The fishery for the Atlantic sea scallop *Placopecten magellanicus* (Gmelin 1791) began in the United States in the mid-Atlantic region in the 1920s and expanded in the 1930s with the discovery of large concentrations of scallops on Georges Bank (Bourne 1964, Serchuk et al. 1979). Commercial landings increased rapidly following World War II, and reached a peak of 17,174 metric tons of meats valued at over $145 million in 1990 (NOAA 1991).

Despite high levels of exploitation and fluctuating annual landings, the first fishery management plan (FMP) for the sea scallop was not in place until 1982 (NEFMC 1982). Objectives of the original sea scallop FMP were to be achieved by controlling the age at entry of the scallops into the fishery. An average meat count restriction of not more than 30 meats per pound (MPP) was enforced for vessels that landed shucked meats. For vessels landing shell stock, a minimum shell size was set at 88.9 mm (3.5 inches).

Several amendments were made to the FMP to correct perceived inadequacies and enforcement difficulties; however, the FMP remained relatively unchanged until 1994. Many of these problems with the original sea scallop FMP are discussed by Naidu (1987), Shumway and Schick (1987), Smolowitz and Serchuk (1987, 1988), DuPaul et al. (1989), Kirkley and DuPaul (1989), and Schmitzer et al. (1991). One major problem of the 1982 FMP was the attempt to manage a fishery that extends over a wide geographic area based on a single parameter of the animal, the adductor muscle size. Size of the adductor muscle has been found to vary widely between resource areas, water depths, seasons, and within the reproductive cycle (Haynes 1966, Shumway & Schick 1987, DuPaul et al. 1989), and this confounded management efforts.

In March 1994, Amendment 4 to the sea scallop FMP was implemented to replace existing MPP restrictions. Amendment 4 restricted fishing effort by limiting vessel days at sea, crew size, the size of the fishing gear, and entry of new vessels into the fishery. Age at entry controls were implicitly imposed by increasing the size of the scallop dredge rings and the mesh of the scallop trawl nets (NEFMC 1993). The primary gear restriction of Amendment 4 increased the minimum ring size of the dredge from 76.2 mm (3.0″) to 82.6 mm (3.25″) for 1994 and 1995, and to 88.9 mm (3.5″) beginning January 1, 1996. Previous gear trials have shown that increasing dredge ring size or trawl mesh size allows an increased escapement of smaller-sized scallops (Medcof 1952, Bourne 1965, Smolowitz & Serchuk 1988, DuPaul et al. 1988, DuPaul et al. 1989).

In this paper we present an assessment of the effects of an increase in dredge ring size on aspects of selectivity, harvesting efficiency, and delay of entry into the fishery. The study targeted the very large 1990 year class of scallops (NEFSC 1993). We found that an increase in scallop dredge ring size will increase escapement of small, pre-recruit scallops less than 70 mm and will delay entry of scallops greater than 70 mm into the fishery. This regulatory measure could lead to substantial increases in yield and spawning potential of specific year classes of scallops.

MATERIALS AND METHODS

Data Collection

Data for this study were collected during four trips aboard commercial scallop vessels (June, August, and November 1994 and April 1995), each lasting 7 to 14 days. Sampling was conducted aboard the fishing vessel (F/V) *Carolina Breeze* and the F/V *Stephanie B* in the Delaware/Maryland/Virginia region of the western mid-Atlantic (NAFO statistical area 6, Fig. 1). Both vessels are approximately 23.01 m (75.5 feet) in length. Catches were sampled from 209 of the 759 tows conducted with the experimental gear.

The fishing gear used during these experiments was the standard offshore New Bedford style scallop dredge used by most vessels in the fishery. Posgay (1957) provides a general overview of the gear, and a more detailed description is given in Bourne (1964). For each trip, the control gear was constructed from 82.6-mm (3.25″) rings, the size used in the fishery at the time of the study. The experimental gear was constructed from 88.9-mm (3.5″)

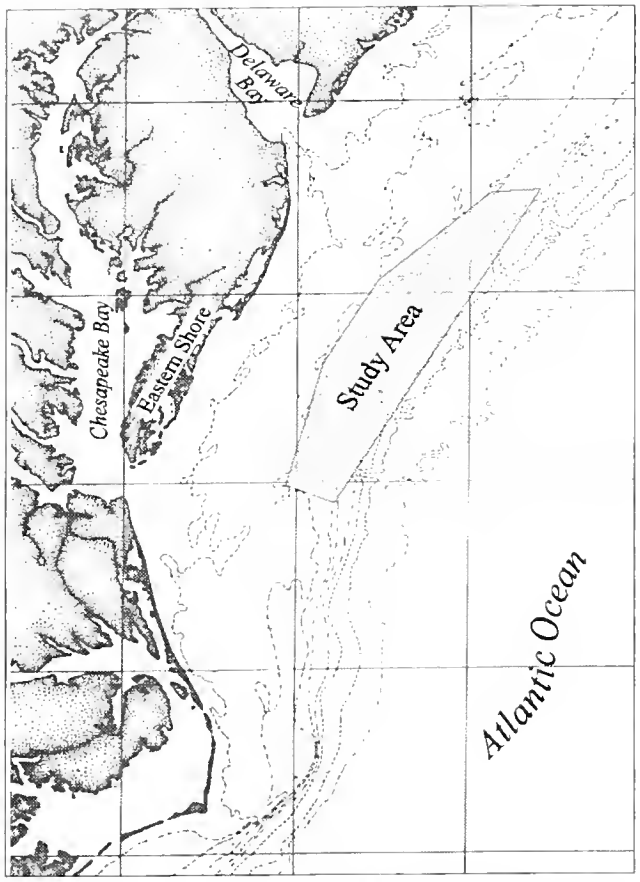

Figure 1. Location of sampling efforts in the Mid-atlantic region.

rings. Both vessels used are capable of towing two dredges simultaneously. Since studies have shown that there is no statistical difference in catch for dredges towed in pairs (Bourne 1965, DuPaul et al. 1989), the control and experimental gears were towed simultaneously. The *Carolina Breeze* towed two 4.27-m-(14-foot) wide dredges, and the *Stephanie B* towed two 3.96-m-(13-foot) wide dredges.

Data collection methodology was similar to that of Bourne (1965) and DuPaul et al. (1989). Sampling procedures were designed to allow usual commercial operating procedures, except that catches from the two dredges were kept separate throughout the trip. For sampled tows, the crew was allowed to cull out the commercial-sized scallops. The remaining bycatch was then sorted to retrieve undersized or discarded scallops. Up to two baskets (1 basket is approximately 1.5 bushels) of commercial-sized scallops, and at least a portion of the discards were retained from each dredge for shell height frequency sampling. Shell height, the maximum distance from the umbo to the ventral margin of the shell, was measured to the nearest 5-mm interval using National Marine Fisheries Service scallop measuring boards.

Six one-basket samples of scallop shell stock were obtained from commercial scallop vessels between February and May 1994 to collect shell height and meat weight data. Each sample represented a single trip by a single vessel. When these scallops were shucked, the upper (left) valve was measured to the nearest millimeter using a measuring board, and the respective meat was weighed to the nearest 0.1 g using an Ohaus CT 600 electronic scale.

Data Analysis

To compare catches from the different trips, the data were standardized to a common unit of effort equal to 50 h of tow time using a 3.96-m wide dredge using the following equations:

$$N_{ij} = (n_{ij}/b_j) \times B_j \tag{1}$$

$$SPH_{ij} = N_{ij} \Big/ \left(T_j/_{60}\right) \tag{2}$$

$$SC_i = \sum_{j=1}^{ST} SPH_i \Big/ \left(ST/_{50}\right) \tag{3}$$

where N_{ij} = the total number of scallops at shell height i in tow j; n_{ij} = the number of scallops sampled at shell height i in tow j; b_j = the number of baskets sampled in tow j; B_j = the total number of baskets in tow j; SPH_{ij} = the number of scallops caught per hour at shell height i in tow j; T_j = tow time in minutes of tow j; SC_i = standardized number of scallops caught at shell height i for the trip; and ST = the number of tows sampled during the trip.

For data from the trip using the 4.27-m-wide dredges, n_{ij} was multiplied by 13/14 to standardize to a 3.96-m-wide dredge before using the above equations.

Harvest efficiency of scallops from the 1990 year class was determined for the 88.9-mm ring dredge relative to the 82.6-mm ring dredge for each 5-mm shell height interval within the year class and for the year class as a whole. This was done by dividing the number of scallops caught in the larger ring dredge by the number caught in the smaller ring dredge. Efficiency estimates for the individual shell height intervals were then smoothed using a moving geometric mean of three (Pope et al. 1975, Serchuk & Smolowitz 1980, DuPaul et al. 1989).

The range of the shell height intervals used for the year class was found using the Petersen method (Jearld 1983). Year classes were distinguished by different peaks in the shell height frequency distributions for scallops from all trips, except the April 1995 trip. In April 1995, the 1991 year class distribution overlapped slightly with the 1990 year class distribution. The 1990 year class was delineated by finding the modal shell height of the year class and visually estimating the right tail of the distribution. It was then assumed that the number of size classes present on each side of the mode was the same.

The conventional allometric or shell height:meat weight model was estimated using SAS software (version 6.09). A log-log transformation was necessary to allow estimation of the relation using ordinary least squares. A random effects model was run, with time of collection being the random variable, in order to combine the samples and obtain a common shell height:meat weight relationship. The model can be expressed as:

$$\ln(MW) = \ln(a) + b \times \ln(SH) + u \tag{4}$$

where "ln" is the natural logarithm, MW and SH are meat weight and shell height respectively, and the error term u is $N(0, \sigma^2)$.

Scallop growth was estimated by applying an exponential growth model to catch data collected during different trips, including data from a trip taken in November 1993 (DuPaul & Kirkley 1994a, DuPaul & Kirkley 1994b). It was during the November 1993 trip that the 1990 year class first started to recruit to the 76.2-mm ring dredge used at the time (DuPaul & Kirkley 1994a). The growth model can be expressed as

$$SH_t = SH_0 \times \exp[G \times (t - t_0)] \quad (5)$$

where SH_t is shell height at time t, SH_0 is shell height at time 0, and G is the exponential growth coefficient.

The mean shell height of the specified age class from each of the trips was plotted against number of days relative to the first sampling trip. It was assumed that daily growth of scallops during each trip was minimal, and that for each trip, all scallops were collected on one day. The first day of each sampling trip was arbitrarily designated the collection day. All increments in days were counted from the first day of the first trip to the first day of each successive trip.

Results of the efficiency, growth, and shell height:meat weight calculations were used to examine the effects increasing ring size to 88.9 mm might have on yield-per-recruit (YPR) of the fishery. The YPR calculations assume only scallops 70 mm and larger are retained by the fishermen. The June 1994 trip was used as a reference point, and the catch in the 82.6-mm ring dredge during that trip was assumed to be a representative sample of the shell height frequency distribution of the year class. Catch in the 82.6-mm ring dredge in June 1994 was multiplied by 10 to give an arbitrary initial abundance of the year class (N_0). Values of fishing mortality (F) and natural mortality (M) were set at $F = 1.5$ (NEFMC 1993) and $M = 0.1$ (Dickie 1955, Merrill & Posgay 1964) for a full year (0.75 and 0.05, respectively, over 6 mo). The year was broken into two 6-mo periods, and the equation

$$N_t = N_0 \times e^{-F \times t} \quad (6)$$

was applied to find population size at time $t = 6$ mo. At the end of each 6-mo period, the remaining population (N_t) was reduced by the natural mortality rate to find the N_0 for the next period. The growth coefficient was applied to the scallops comprising the new N_0 to obtain the new shell height frequency distribution. These calculations were repeated four times to simulate harvest over a 2-y period (0–6, 6–12, 12–18, and 18–24 mo). Catch for each period was estimated from $C = N_0 - N_t$. The shell height:meat weight model was applied to the harvest at each shell height for each repetition and was summed over all repetitions to finds landings for the entire period.

To estimate landings for the 88.9-mm ring dredge, similar methods were used except that the catch was adjusted by the relative efficiency at each shell height. N_t was found as $N_0 - C$, and then reduced by the natural mortality rate to give N_0 for the next period.

Spawning potential (in terms of overall fecundity of each animal) was estimated using residual reproductive value (RRV) (MacDonald 1984). RRV takes into consideration the probability of a scallop surviving between successive spawning events. The probability of survival between ages X and X + 1 is multiplied by the fecundity at age X + 1. Overall fecundity was found as the sum of fecundity at age X plus the RRV of fecundity at age X + 1.

RESULTS

Relative Efficiency

Harvest by each of the ring sizes during each of the trips is shown for each shell height standardized to 50 h of tow time in Table 1. Estimates of relative harvest efficiency by the 88.9-mm ring dredge ranged from 60% to 72% over the study period (Table 2). Examination of the efficiency estimates by shell height (Table 3) indicated that scallops from the 1990 year class would be captured with 90% to 100% relative efficiency when they reach 100 to 105 mm shell height. Harvest by the larger ring dredge exceeded harvest by the smaller ring dredge for several of the larger shell heights, but then decreased. With the exception of the November 1994 trip, relative efficiency increased for larger scallops. The unusually large decrease in efficiency in November 1994 is not readily explainable, but has been observed and documented during other gear trial studies (DuPaul et al. 1989).

Shell Height: Meat Weight and Growth

Six one-basket samples of scallop shell stock were obtained between February and May 1994 for use in shell height:meat weight analysis. Each sample represented a single trip by a single vessel. A random effects model was run, with time of collection being the random variable, in order to combine the samples and obtain a common shell height:meat weight relationship. The relationship found is shown below. The values under the equation are the t values for the coefficients.

$$\ln(MW) = -9.7776 + 2.6996 \times \ln(SH) \quad (-73.604)\ (98.136) \quad (7)$$

The estimates of the daily growth coefficient between successive trips are shown in Table 4. The overall estimate for the daily

Overall		47,596	31,542	0.66

growth coefficient ($G = 0.000736$) was used for all growth calculations in this paper.

YPR and Spawning Potential

Applying the shell height:meat weight relationship to the shell height frequency distribution of the 1990 year class observed in June 1994 results in approximately 490 kg of meats. Delaying harvest by 1 y (assuming knife-edge selectivity) would yield approximately 844 kg of meats, assuming $M = 0.1$ and relative efficiency is 90%. This is an increase in yield of more than 70%. The offshore scallop dredge, however, does not perform with knife-edge selectivity. When size-specific relative efficiency is considered over a 2-y period, yield from the larger ring dredge was approximately 8.3% more than the smaller ring dredge (Table 5). Based on analysis of cumulative fecundity of scallops ages 3 and 4 using residual reproductive values, increases in fecundity were estimated to range from 43% to 59% higher when the 88.9-mm ring dredge is used and more scallops are present to spawn at age 4 (Table 6).

DISCUSSION

When Amendment 4 became effective in March 1994, the sea scallop resource was considered to be overfished if spawning stock biomass (SSB) was below 5% of that of an unfished population. The optimum level of fishing mortality relative to the SSB threshold definition ($F_{5\%}$) was determined to be 0.97 (NEFMC 1993). A 1997 review of the sea scallop resource found that fishing mortality in the Mid-Atlantic had been above the overfishing definition since 1985 (NEFSC 1997). Higher than sustainable levels of fishing effort decreased the abundance of sea scallops, and subsequently, the number of exploitable year classes available to the fishery. This created the situation where the fishery is highly dependent on the recruiting year class (Serchuk et al. 1979, Brown 1987, NEFSC 1993, NEFMC 1993). When there are limited exploitable year classes, a fishery may be detrimentally affected by continued exploitation.

Gear regulations contained in Amendment 4 were implemented primarily to lower fishing mortality on small scallops and delay age at entry into the fishery. Data from this study suggest that the 88.9-mm rings will achieve these goals and also improve yield per recruit in the fishery and increase SSB of the scallop stock. The 88.9-mm dredge rings were anticipated to be an important factor in reducing fishing mortality to below the overfishing definition and meeting the management objectives, when used in conjunction with the other management measures.

Relative Selectivity, Efficiency, and Age at Entry

The year class targeted during this study was the largest year class on record to recruit to the Delaware/Maryland/Virginia region (NEFSC 1993). As many as 25 baskets (35–40 bushels) of these scallops were caught per tow in a single dredge during a sampling trip in November 1993 (DuPaul & Kirkley 1994a, Du-

TABLE 4.

Estimates of the exponential growth parameter (G) for the 1990 year class for each trip and for all trips combined.

Trip Date	Mean Shell Height (mm)	Interval Between Trips (days)	Cumulative Interval (days)	Growth Coefficient ($\times 10^{-4}$)
November 1993	62.16		0	
June 1994	78.87	217	217	10.97
August 1994	80.17	67	284	2.44
November 1994	82.03	75	359	3.06
April 1995	92.50	181	540	6.64
Overall		540	540	7.36

Paul & Kirkley 1994b). The majority of these scallops were 60–65 mm and averaged 100 MPP. Larger individuals from this year class were already being retained by the fishermen (DuPaul & Kirkley 1994a).

Amendment 4 increased the ring size used in the scallop dredge initially from 76.2 to 82.6 mm, and subsequently to 88.9 mm. DuPaul and Kirkley (1994a, 1994b) have shown that the 82.6-mm ring dredge decreased efficiency of the scallop dredge (in terms of number of baskets caught) by 12% on soft bottom (sand and mud) to 45% on hard bottom of cobble, relative to the 76.2-mm ring dredge. During the present study, harvest efficiency of the 88.9-mm ring dredge relative to the 82.6-mm ring dredge (in terms of number of scallops caught) ranged from 60% to 72% (Table 2).

For this study, full recruitment (retention) to the experimental gear was considered to be reached when 90% efficiency relative to the 82.6-mm ring dredge was attained. For example, 90% to 100% relative efficiency was reached when scallops were 100–105 mm shell height (Table 3). Using the June 1994 modal shell height of 77.5 mm as a reference point, and by applying the estimated growth equation determined in this study, it would take the 1990 year class 346 days, or nearly a year to reach the size of 100 mm and thus be fully retained by the 88.9-mm ring dredge.

YPR

Many studies have examined the effects of delaying harvest as a means to increase YPR in terms of meat weight in the scallop fishery (e.g., Posgay 1958, Posgay 1962, Caddy 1972a, Caddy 1972b, Posgay 1979, Serchuk et al. 1979, Sinclair et al. 1985). Posgay (1979) and Serchuk et al. (1979) estimated that maximum YPR is attained by harvesting 8-year-old scallops. Serchuk et al. (1979), however, suggest that scallops be harvested when they reach age 6, since delaying harvest past this age results in only minor additional increases in YPR. Previous studies have shown that an increase in age at first capture from age 5 to age 6 will result in an increase in YPR of 10% to 20% (Posgay 1962, Serchuk et al. 1979; Table 7). Delaying harvest from age 4 to age 5 will increase YPR by as much as 50% (Sinclair et al. 1985). By the early 1990s, age at first capture had decreased to between ages 3 and 4. It is, therefore, important to investigate the changes in yield that could be expected by delaying harvest to age 4 or older.

TABLE 5.

Estimates of yield (kilograms) over a 2-y time period using the 82.6- and 88.9-mm ring dredges.

Time Period	82.6-mm Rings	88.9-mm Rings
0–6 mo	2,236.53	1,463.82
6–12 mo	1,524.88	1,546.34
12–18 mo	984.35	1,639.49
18–24 mo	634.99	1,178.42
Total	5,380.75	5,828.07

Assuming knife-edge selectivity and no changes in commercial culling size and shucking capacity, delaying harvest from age 3 to age 4 would increase yield in the fishery by nearly 75%. These conclusions are consistent with those presented in other studies that examined YPR for similar sized scallops (Table 7). The offshore scallop dredge, however, does not perform with knife-edge selectivity, and partial recruitment results in the capture and shucking of small scallops. When partial recruitment is considered in the analysis, and fishing mortality of $F = 1.5$ and natural mortality of $M = 0.1$ are assumed, the 88.9-mm ring dredge would increase yield no more than 10% (Table 5).

Our results indicate that advances in yield made possible by gear changes have to be optimized with additional measures to reduce fishing mortality and effort. Posgay (1979) concluded that a cull size of age 5 (95 mm) was too young and the fishing mortality ($F = 0.7$) was too high to achieve maximum yield for the Georges Bank scallop resource during the 1960s. Currently, in the mid-Atlantic fishery, age at recruitment is younger and fishing mortality is higher than on Georges Bank in the 1960s. Increasing ring size to 88.9 mm can increase the yield in the fishery, but additional measures to decrease fishing mortality and effort must be implemented in order to attain the maximum YPR.

Spawning Potential and Spawning Stock Biomass

Data from this study show the larger ring dredge has the potential to improve scallop SSB, which has been depressed due to high exploitation rates, drastically reducing the number of age 4 and 5 scallops. Scallops are sexually mature by the end of their third year (NEFMC 1993), and fall spawning generally occurs between late August and December (Posgay & Norman 1958, MacDonald & Thompson 1986, DuPaul et al. 1989, Schmitzer 1990). It is during this period that the faster growing 3-year-old scallops begin to recruit to the 76.2-mm gear. Most scallops spawn at this time, but the 3-year-old scallops do not contribute significantly to the overall fecundity of the resource (McGarvey et al. 1993). Even considering partial recruitment, the larger dredge rings will decrease harvest of age 3 scallops and allow more scallops to spawn at age 4. Because fecundity of sea scallops increases exponentially with size for several years after first reaching sexual maturity (MacDonald & Thompson 1985, Langton et al. 1987, Carnegie 1994), the delay in harvest should increase the overall fecundity of the resource (Table 6). In addition, McGarvey et al.

TABLE 6.

Estimates of residual reproductive value (RRV) assuming 10% natural mortality and 66% harvest efficiency between ages 3 and 4.

Reference	Study Area	Age (y)	RRV (millions of eggs)	Cumulative Fecundity (millions of eggs)
MacDonald 1984	Sunnyside, Newfoundland	3	4.95	4.95
		4	2.59	7.54
Langton et al. 1987	Boothbay, Maine	3	9.30	9.30
		4	3.96	13.26
MacDonald and Thompson 1986	New Jersey	3	5.49	5.49
		4	3.24	8.73

(1993) found a statistically significant relationship between the number of spawners and recruits for Georges Bank scallop stocks. Delaying harvest by using the larger rings could therefore lead to increases in overall stock abundance and concomitant increases in SSB.

Conclusions

The effects of increasing dredge ring size are strongly dependent on the amount of fishing effort in the study area. A decrease in fishing effort would increase the benefits of the larger ring size, while increasing effort would reduce the positive effects of the larger rings. Analysis conducted for this study suggest that the 88.9-mm dredge rings should provide many benefits to the sea scallop fishery and resource, and combined with the other regulations defined in Amendment 4, should have helped achieve several of the objectives outlined in the FMP. The benefits of the larger ring size suggested by this study have not been realized, however. This is most likely due initially to management measures for other species, and subsequently, similar measures for scallops.

In December 1994, the use of mobile fishing gear, including sea scallop dredges, was prohibited in certain areas of Georges Bank (Closed Area I and Closed Area II) and southern New England (Nantucket Lightship Closed Area) in order to allow severely depleted groundfish stocks to rebuild (NEFSC 1997). Much of the fishing effort previously targeting scallops on Georges Bank was displaced to the southern New England and mid-Atlantic regions, which remained open. Fishing effort substantially increased in these regions (NEFSC 1997). In April 1998, at the request of the New England Fishery Management Council, the Secretary of Commerce closed two additional areas in the mid-Atlantic to scallop fishing to protect small scallops. Recently, the NEFMC (1997) determined that fishing mortality on scallops is still above the overfishing definition, and the closure of these 1,900 square miles in the mid-Atlantic only concentrates fishing effort into the remaining open areas.

Modifications to scallop fishing gear designed to reduce the harvest of small scallops and advance the age of entry can be an important management tool, but are most effective when used in conjunction with measures to reduce or stabilize fishing effort and mortality. Data from this study suggest that increasing scallop dredge ring size can decrease mortality of small scallops and postpone recruitment of scallops to the commercial fishery. The delay in recruitment can lead to increases in fishery yield and spawning potential of the resource. The potential benefits of the recent gear modifications, however, have been diminished due to increased fishing effort in the area. In order to realize the full benefits of increasing scallop dredge ring size, the gear restrictions must be associated with measures to stabilize or decrease fishing mortality and fishing effort.

ACKNOWLEDGMENTS

This research was submitted to the Virginia Institute of Marine Science, College of William and Mary (Gloucester Point, VA) by J. B. in partial fulfillment of the Degree of Master of Science. The authors would like to thank Captains Andrew Benevidez (*Stephanie B*) and Juan Araiza (*Carolina Breeze*) and their crews for allowing us to work on their vessels, and the many captains and crews that provided shell stock for this research. J.B. would like to thank Colleen Brust, Geoff White, and Ryan Carnegie for their assistance in the laboratory and field, and for their continued support throughout the research. We appreciate the constructive and insightful comments that were received from two anonymous reviewers. This is contribution No. 2397 from the Virginia Institute of Marine Science.

EFFECTS OF DEPLOYMENT TIME AND ACCLIMATION ON SURVIVAL AND GROWTH OF HATCHERY-REARED SCALLOP (*PECTEN MAXIMUS*) SPAT TRANSFERRED TO THE SEA

GYDA CHRISTOPHERSEN AND THOROLF MAGNESEN

Centre for Studies of Environment and Resources, University of Bergen, Norway

ABSTRACT Hatchery-produced great scallop (*Pecten maximus*) spat of 1 to 5 mm shell height were transferred to a sea-based nursery from March to August 1995. Because the growth season in Norwegian waters is limited by low sea temperature in the spring (5°C–10°C), acclimation to a colder temperature (10°C) than the 15°C in the hatchery was considered in order to enhance survival after deployment. Survival and growth of spat deployed directly to the sea were compared with spat acclimated for 1 and 3 wk. Results indicated that specific growth rates were 1% to 3% per day. Mean survival of acclimated groups was 0% to 9% for small spat (0.7–2.3 mm) and 25% to 36% for bigger spat (4 mm). Acclimation improved mean survival by up to 7% of the small spat and 11% of the bigger spat. An extension from 1 to 3 wk acclimation did not further improve survival or growth. Duration of exposure to low temperatures (<10°C) and temperature at deployment time were main factors affecting survival and growth considering all spat groups, while size at deployment mainly determined the success for acclimated scallops. Less than 5% of the smallest spat survived when directly transferred to sea temperatures of 5°C to 7°C. Larger spat obtained 25% mean survival, which is comparable with 24% to 60% survival of spat transferred to sea temperatures ≥10°C. Shell growth rate likewise was elevated when the temperature exceeded 10°C. Acclimation to a lower temperature gave only limited increase in survival, and it was determined that small spat (<2.6 mm) should not be transferred to temperatures <7°C. By deploying bigger spat (>4 mm) to low sea temperatures, high survival can be expected, and thereby the production period is extended.

KEY WORDS: acclimation, nursery culture, *Pecten maximus*, scallop spat, survival, growth

INTRODUCTION

Stable spat supply to growers is the main constraint in the development of a scallop cultivation industry. Due to overfishing of scallop populations around the world, and to the fact that scallops are high-value products, the establishment of hatcheries for ensuring a reliable production of spat has become important to the industry. Intensive larval growth in a hatchery is usually followed by growth to commercial-sized spat in semi-intensive growth systems termed "nurseries." A nursery can be sea- or land-based, depending on natural seawater supply or cultured algae as a food source. In cold water areas like the North Atlantic, the growth season in the sea is limited by environmental factors such as the low temperature in the spring. The longer the period of the year in which scallops can take advantage of the natural food production, the more beneficial it is to producers. Making spat available earlier in the year and providing growers with larger spat at the optimum time in the growth season would ease the constraint.

Scallops are shown to be susceptible to small changes in temperature (Dickie & Medcof 1963, Strand et al. 1993, Chauvaud et al. 1998), but their tolerance limits varies with species and natural habitat (Brand 1991). Scallops are more sensitive to environmental changes compared with intertidal bivalves like mussels, oysters, and clams because they are not able to completely close their valves when encountering unfavorable conditions. Changes in temperature may have a direct or indirect impact on survival. Temperature drops of 4°C to 7°C have been shown to cause immobility of sea scallops, which in their natural environment could increase vulnerability to predators and thereby increase mortality (Dickie 1958). Abrupt and considerable changes in environmental conditions are likely to occur in an aquaculture situation during handling and transfer operations. The transfer from hatchery conditions to colder temperature conditions in the sea for nursery growth may therefore be hazardous.

In culture, both the thermal and the nutritional conditions will affect scallop growth performance (Ventilla 1982, Wallace & Reinsnes 1985, Andersen & Naas 1993, Couturier et al. 1995, Pilditch & Grant 1999, Grecian et al. 2000). Exposure to cold water temperatures of <10°C have been shown critical for the great scallop, *Pecten maximus*, at different stages. High mortality of veliger larvae occurs at 7°C to 8°C, and at 5°C, total mortality may be expected (Davenport et al. 1975, Beaumont & Budd 1982). For *P. maximum* juveniles of 20 to 30 mm shell height (SH), a reduction in filtration rate of 50% to 80% was recorded at 5°C compared with 9°C (Strand et al. 1993), and Laing (2000) found no growth or measurable uptake of food at 4.7°C by 5 to 14 mm spat. A 100% mortality at <4°C is reported from growth trials in suspended intermediate culture in Norway (Brynjelsen & Strand 1996), while a temperature of 9°C is suggested as a "biological zero" for shell growth in Irish waters (Wilson 1987).

Acclimation may be a successful way to adjust an animal to different conditions. A three-phase process consisting of an immediate response, a stabilization of this response, and a new steady state can explain the adaptation to new surroundings (Kinne 1963). Studies of the sea scallop have indicated that a rise or fall in acclimation temperature of about 5°C may result in a corresponding change in lethal temperature of 1°C (Dickie 1958). The rate of acclimation tends to follow the rate of metabolism, resulting in longer time needed for acclimation to a decrease in temperature than an increase. The animals' environmental history, genetic background, physiological condition, metabolism, age, and size are all factors affecting the capacity, rate, and effect of thermal acclimation (Kinne 1963, Schmidt-Nielsen 1990).

One method for producing *P. maximus* spat in Norway is intensive hatchery rearing to approximately 2 mm SH at a temperature of 15°C, before further growth to 15 mm in a sea-based nursery. Transfer to the sea is restricted to the period from June to August for the spat to reach a commercial size within one season. A prolonging of the production period would be possible if a method was found to successfully transfer the spat to the sea earlier in the spring when the temperature is low. The prevailing method of transferring spat from the hatchery is by directly deploying the spat to the sea. Acclimation of spat to an environment of 10°C with subsequent transfer to temperatures between 5°C and

10°C was considered a possible solution to ensure that scallop spat would tolerate transfer to the sea during the spring.

The aim of this study was to determine whether exposing the spat to a temperature between the hatchery and the sea temperature, before transfer to the sea in the spring, could enhance survival. Spat groups that had been subjected to the prevailing production method of directly deployment to the sea were monitored throughout the season, and survival and growth rates were compared with spat groups acclimated for 1 and 3 wk.

MATERIALS AND METHODS

The study was carried out during spring and summer 1995 in Oygarden, Hordaland County, western Norway, with spat originating from broodstock collected from the wild. During the period from October 1994 to June 1995, groups of 40 to 60 scallops were conditioned, induced to spawn, and cross-fertilized. Spat of 1 to 5 mm SH were obtained by standard production methods at Oygarden Scallop Hatchery. Survival and growth of spat from 10 different spawning groups (1–10) were determined after deployment to the sea throughout the production season. Spat from spawning groups 3 through 6 were subjected to acclimation treatments for 1 and 3 wk before transfer to the sea (Table 1). For some of the spawning groups, more spat groups of different age and size (A, B, and C) were deployed (Table 1).

Prior to deployment, the spat were removed from 140-μm mesh screens, which served as bottom of cylindrical growth containers or sieves (1,225 cm^2), by gentle brushing in a flow of water, and they were relayed onto plastic trays (60 × 60 × 8 cm) covered with 500 μm mesh. The trays were kept overnight in running seawater, allowing resettlement of the spat. Stacks of four trays, consisting of three experimental trays plus one as lid, were suspended from long lines in the sea at a depth of 8 to 10 m. Grow-out in the sea was within the period from March 1 to September 29 (Table 1). The growth time varied according to deployment date, as the spat grew to a size of 5 to 10 mm, big enough for grading and restocking.

Acclimation took place under conditions of lower temperature and food concentration than were used prior to the treatment. The spat were kept at 10°C and were fed 10 cells per μl of a mix of the monocultured algae *Pavlova lutheri*, *Isochrysis galbana*, and *Skeletonema costatum* in a 1:1:2 ratio, compared with 15°C and 15 to 20 cells per μl, respectively. The spat groups (3, 4A, 4B, 5, and 6A) subjected to acclimation were divided into three subgroups, each consisting of three sieves. One subgroup was deployed directly to the sea without acclimation. The second subgroup was deployed after 1 wk of exposure to acclimation conditions, and the third was transferred after 3 wk of acclimation. Because of limitations in the hatchery, the spat were transferred directly from hatchery conditions to acclimation conditions without a gradual habituation to the lower temperature.

Survival was estimated as the difference in numbers of animals at deployment time and the numbers retained on a 3-mm screen after 52 to 134 days grow-out in the sea. The initial number in each sieve was estimated by counting the spat of a 50 × 1 cm^2 (4%) area of the mesh bottom and multiplying to the total area. The final numbers were estimated by wet weight measurements based on counting subsamples of 100 spat from the trays.

Growth in the sea was based on mean SH measurements of 50 animals from each sieve at deployment time and from each tray at uptake date. Spat growth during the acclimation period was also measured. Final size of the bigger (4B, 4C, 6B, and 6C) deployed spat was determined by using the weighted average of means from two size groups (3–10 mm and >10 mm). SH growth was calculated as specific growth rate (% day^{-1}): $G = (e^{g} - 1) \times 100$, where the instantaneous daily growth coefficient $g = (\ln SH_{final} - \ln SH_{initial})$ per days (Ricker 1979, Claus 1981).

Sea temperature and salinity were measured weekly with a WTW Microprocessor Conductivity Meter (LF196) (Wissenschaftlich-Technische Werkstätten G.M.B.H. D-8120, Weilheim, Germany) connected with a WTW conductivity-measuring cell (TetraCon 96 A-4). Food concentration in the sea was measured occasionally using an electronic particle counter (Model ZM Coulter Counter, Coulter Electronics Limited, Luton, England).

The statistical analyses were carried out using STATISTICA®, version 5, and a significance level of 0.05 was applied to the tests. Analysis of variance (ANOVA) was performed on the growth and survival data of the spat that were acclimated, and treatments showing significant differences were further characterized by the Tukey HSD test. The survival data (percentage) of the spat were arcsine transformed before statistical analysis to obtain variance homogeneity for all groups (Sokal & Rohlf 1995). Pearson product-moment correlation coefficients were calculated for shell parameters and grow-out conditions in the sea. Multiple forward stepwise regression analysis was performed for all the spat groups transferred to the sea and for acclimated groups separately. Survival (percentage) and specific growth (percentage per day) were related to the variables; acclimation time, size, density, and sea temperature at deployment time, and the period of exposure to temperatures <10°C during grow-out in the sea.

RESULTS

Seawater Conditions

Sea temperature at the grow-out depth of 8 m increased from 5°C to 15°C during the experimental growth period (Fig. 1). The temperature reached 7°C in the beginning of May and exceeded 10°C in June. Salinity varied between 30 and 33 with occasional drops below 30‰. A salinity of 27.6 was the lowest recorded during the period from June to October (Fig. 1). The number of 2- to 10-μm particles at 8 m was below 10 cells per μl in March and April. In the beginning of July, the natural food production had increased, and 50 cells per μl was measured.

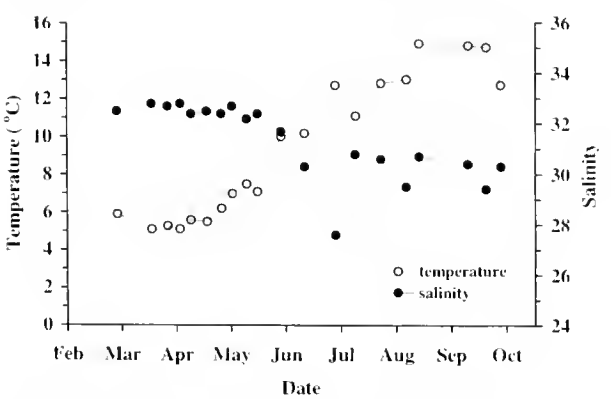

Figure 1. Temperature and salinity at 8 m grow-out depth during the 1995 season, Ulvesundet, Oygarden, Norway.

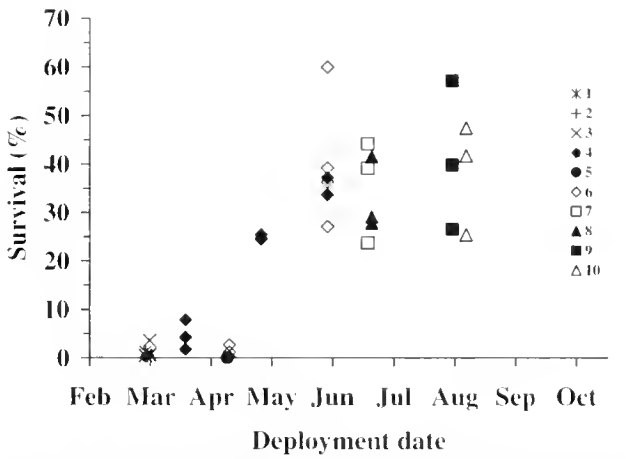

Figure 2. Survival of scallop spat directly deployed to the sea during the 1995 season. Different symbols represent the spat groups number 1 through 10, and each point represents the survival in one tray.

Survival

Survival ranging from 0% to 60% was observed for scallop spat transferred directly from the hatchery to the sea during the 1995 production season (Fig. 2). Dead scallops found upon retrieval passed through the 3-mm screen, indicating that no growth had taken place before mortality occurred. Spat in the size range 0.7 to 2.6 mm directly deployed to a sea temperature below 7°C showed mean survival of less than 5%, while the 4B group, which held a 4 mm SH at deployment, showed 25% survival (Fig. 2; Table 1). A large variation in survival between trays was shown for the spat groups deployed at a sea temperature of 10°C and above. The average survival was 38% (SD = 10.37) for these groups, ranging from 24% to 60% (Fig. 2).

The spat groups (3, 4A, 4B, 5, and 6A) subjected to the acclimation treatment were deployed from March 1 to May 18 when the sea temperature ranged from 5°C to 7°C (Table 1). Mean survival rates from 0% to 9% were obtained for the spat groups of initial average size 0.7 to 2.3 mm. For the 4-mm spat group (4B), mean survival rates of 25% to 36% were found (Fig. 3). Compared to

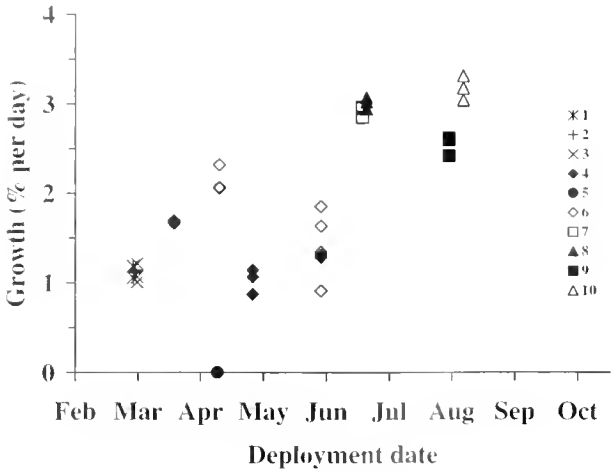

Figure 4. Specific growth rate (percentage of SH per day) of scallop spat directly deployed to the sea during the 1995 season. Different symbols represent the spat groups number 1 through 10, and each point represents the mean growth in one tray.

direct transfer from the hatchery to the sea, acclimation improved the mean survival by up to 7% for the smaller sized spat groups, while the bigger sized group gained a mean increase of 11% (Fig. 3). A one-way ANOVA was carried out for each spat group. The survival of the acclimated spat from the groups number 3 and 4A was not significantly different from the spat deployed directly to sea. For the other spat groups examined, there was a significant difference between the treatments. Survival of the spat transferred directly to the sea was significantly lower than the survival of acclimated spat. Extension of the acclimation time from 1 to 3 wk did not improve survival significantly for any of the spat groups.

Growth

Specific growth rates of the spat deployed to the sea without foregoing acclimation were found to be in the order of 0.9% to 3.3% or 46 to 128 μm increase in SH per day (Fig. 4). No surviving scallops were observed for spat group 5 (Fig. 2), which consisted of the smallest spat deployed during the experiment (Table 1). Hence, no growth could be calculated for this group.

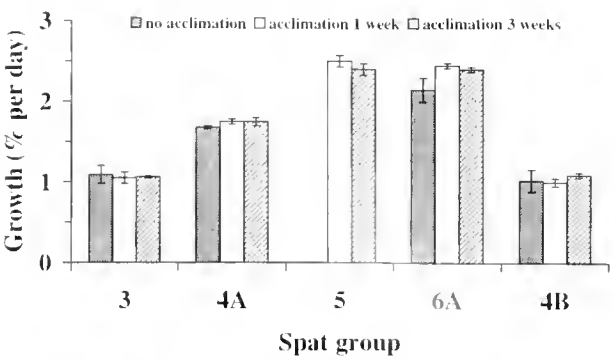

Figure 5. Mean specific growth rate (percentage of SH per day) of scallop spat during the total experimental period (acclimation time included). The spat were deployed directly to the sea (no acclimation) and after 1 and 3 wk of acclimation. Vertical bars show standard deviation.

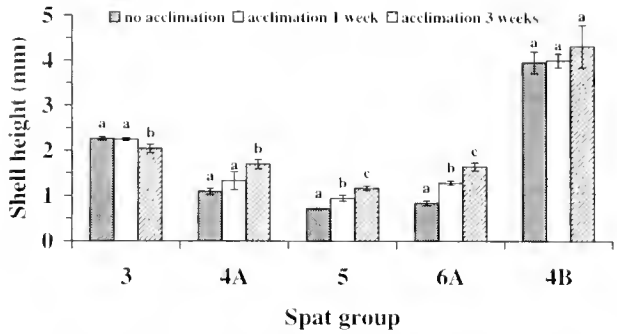

Figure 6. Mean SH at deployment time of scallop spat subjected to acclimation treatments. Subgroups of spat were deployed directly to the sea (no acclimation) and after 1 and 3 wk of acclimation. Values indicated by different letters within each spat group are significantly different. Vertical bars show standard deviation.

The mean final size of the spat groups surviving direct transfer to the sea was 9.1 mm (SD = 1.74). The SHs ranged from 3 to 21 mm.

The mean specific growth rates obtained for the spat groups subjected to acclimation were between 1.0% and 2.5% per day during the grow-out period in the sea, as for the total experimental period, acclimation time included (Fig. 5). The statistical tests showed that acclimation of the spat group 6A significantly improved the growth rate during the total experimental period, and of the spat from group 3 acclimated for 3 wk, considering the grow-out phase in the sea. An extension of the acclimation time from 1 to 3 wk did not result in faster growth for any other spat groups. The SH at time of deployment to the sea differed between the subgroups, and except for group 3 and 4B, the spat groups subjected to acclimation treatment showed growth during the acclimation period (Fig. 6). Upon retrieval, the differences in average SH were evened out, with the exception of the 6A subgroup not acclimated, which obtained a significantly smaller size compared with the acclimated ones (Fig. 7).

Correlation and Regression Analyses

Growth rate and survival are related to short grow-out time at higher temperatures (Table 2). Growth rate correlated with small spat, and survival correlated with large spat. Some of the shell and

environmental parameters correlated strongly between themselves, like size and age at deployment, temperature at deployment and during the grow-out period, and grow-out time and temperatures (Table 2). According to the stepwise regression analysis, exposure time to temperatures <10° C and size at deployment explained 80% and 90% of the variation in survival of all groups and acclimated groups, respectively (Table 3). Temperature at deployment ranked above the other variables in explaining the growth rate variation regarding all spat groups during grow-out in the sea. Size was the most important factor for the spat acclimated 1 and 3 wk before

deployment. Density neither had significant effect on survival nor on growth, and acclimation time had no significant influence within the acclimated groups (Table 3).

DISCUSSION

The present study shows that the success of scallop spat is highly dependent on temperature at deployment time. The results indicate that transfer of small *P. maximus* from hatchery to natural sea conditions of temperatures <7°C for long durations is likely to be critical. Survival of the spat deployed directly to the sea increased substantially when the sea temperatures reached 7°C (Figs. 1 and 2). There was a strong positive correlation between survival and temperature, despite the wide variation between trays (Fig. 2; Table 2). Lethal temperatures for *P. maximus* larvae and juveniles, according to other studies, are 8°C and <4°C, respectively (Beaumont & Budd 1982, Brynjelsen & Strand 1996). The spat investigated in our study were sized between larvae and juveniles. On the basis of this, it was assumed that transfer of spat to sea temperatures >5°C would not be fatal. Our observations show that some *P. maximus* spat of <2.5 mm are able to survive transfer to 5°C to 7°C, while others suffer high mortality. The low lethal tolerance temperature for another cold water scallop species, *Patinopecten yessoensis*, is also found to be about 5°C (Ventilla 1982), while the sea scallop, *Placopecten magellanicus*, tolerate temperatures down to below 0°C (Couturier et al. 1995). The lower lethal temperature of scallop spat might not be an absolute temperature but rather a range. Each scallop species is distributed within a certain geographical and bathymetric range where the environmental conditions support survival (Brand 1991). Tolerance limits, therefore, will vary between populations of the same species due to the exposure of different local temperature ranges and seasonal variations. Within a population, a high temperature shown to be lethal to the animal during winter may be tolerated by the animal when exposed to summer conditions and vice versa (Schmidt-Nielsen 1990).

A marked increase in shell growth rates was shown at temperatures above 10°C (Fig. 4; Table 1). Several studies have concluded that temperature rather than food availability is the most important environmental factor affecting scallop growth in the sea (Andersen & Naas 1993, Kleinman et al. 1996, Chauvaud et al. 1998, Laing 2000). Others (MacDonald & Thompson 1985, Wallace & Reinsnes 1985, Thorarinsdóttir 1994, Laing & Psimopoulous 1998) stress the importance of food supply for scallop growth. Which of the two factors are most important could not be determined in our study due to lack of regular food concentration measurements in the sea. The food rations in terms of particle counts were lower from March to May compared with later in the season, but the level was not believed to be growth limiting. Spring bloom events of algae probably ensured enough food since similar growth rates of surviving spat were found both early and late in the season.

The low survival in spring found in our study may also be influenced by environmental factors other than temperature and food availability. More site-specific conditions like salinity, flow velocity, presence of predators, and fouling organisms are shown to affect growth and survival of scallop juveniles (Wilson 1987, Cahalan et al. 1989, Wildish & Saulnier 1992, Andersen & Naas 1993, Lodeiros & Himmelman 1996, Freites et al. 2000, Grecian et al. 2000). Likewise will the different environmental factors synergistically affect the growth performance (Kirby-Smith & Barber 1974, Paul 1980, Strand et al. 1993, Grant 1996, O'Connor & Heasman 1998, Pilditch & Grant 1999). In suspended culture, the scallops are exposed to more fluctuations in food supply, salinity, and temperature compared with their natural habitat on the sea bottom (Tebble 1966). By keeping the animals higher up in the water column, as in our study, the temperature and food amount are elevated during spring and summer. The higher survival and growth observed for spat exposed to summer temperatures was probably a result of increased metabolism together with food available in excess. Oxygen consumption and filtration rate of scallops are known to be temperature dependent (McLusky 1973, Bricelj & Shumway 1991), as are energy metabolism, feeding ability, and growth of bivalves in general (Walne 1972, Bayne et al. 1976, de Villiers et al. 1989, Rice & Pechenik 1992, Grant 1996).

Relatively high growth rates were obtained for the spat deployed in the spring (Fig. 4). The growth was based on measurements of spat that had survived the total 7 to 19 wk grow-out in the sea. Seen together with the complementary low survival of the spat transferred early in the year, the good results are due to a few, but very vital, scallops. The growth rate calculations were based on the total grow-out period in the sea. A longer time span combined with a lower average temperature was expected to give a lower daily growth compared with animals allowed to grow at optimal time in the sea. This was confirmed by the significant negative correlation coefficients found between grow-out time and growth (Table 2).

Acclimation from 15°C to 10°C reduced the negative impact of cold water temperature at deployment. According to the regression analysis, size was the most important factor explaining the variation in survival and growth of acclimated *P. maximus* spat (Table 3). The acclimated spat were transferred to the similar temperature range (5.1°C–7.1°C), which might account for the reduced effect of temperature at deployment. Larger spat (4 mm) showed better survival than smaller spat (<2.6 mm) when transferred to low temperatures. Along with the size at deployment, a shorter time of exposure to temperatures below 10°C might have influenced the results, as this was also shown as an important factor explaining growth and survival variation. Grecian et al. (2000) likewise found initial size to have significant influence on growth and survival of *P. magellanicus* spat transferred to sea-based nursery, showing better results for spat of >3 mm SH compared with spat of 1.2 to 2 mm. For *Pinctada margaritifera* spat, on the other hand, it was found that transfer from the hatchery to the sea should occur as soon as possible after settlement in order to maximize growth (Pit & Southgate 2000).

The scallops found dead upon retrieval in the present work were of a small size (<3 mm SH) compared with the majority of the surviving ones. Mortality is therefore likely to have occurred shortly after deployment time. According to the descriptions of the gill organogenesis by Beninger et al. (1994), the spat in our study were anatomically undeveloped. Beninger et al. (1994) found the gill function of *P. maximus* spat up to 4 mm to be different from the adult gill, and suggested that the development from one size stage to the next is critical in terms of survival. This may explain that the spat of 0.7 to 2.6 mm SH used in our study were incapable of rapid adjustment after transfer to the cold water environment. Poorer feeding ability of the spat deployed to the lowest temperatures in addition to the temperature stress may have caused the mass mortalities observed in spring.

The acclimation to an intermediate temperature between the hatchery (15°C) and the sea (5°C–7°C) prior to deployment in spring enhanced the survival of scallop spat. The present study shows increased mean survival of up to 7% for small spat (0.7–2.3

mm) and 11% for larger spat (4 mm). The overall survival rates of the larger spat were higher and comparable to those obtained for spat deployed later in the season (Figs. 2 and 3). Regarding growth rates of the larger spat, they were relatively low, and no improvement was gained from acclimation (Figs. 4 and 5). These results could be due to the fact that smaller individuals of scallops grow faster than larger ones (Bricelj & Shumway 1991, Parsons et al. 1993) (Table 2), or that growth in sea conditions, in spite of suboptimal temperature, is more favorable than hatchery conditions. With respect to the SH of the spat subjected to acclimation, some growth compensation seems to have occurred in the sea since similar final sizes were achieved for the subgroups (Figs. 6 and 7). The spat of group 5 and 6A not acclimated and directly deployed to a temperature of 5.6°C appeared, on the other hand, not to reveal such growth compensation. One group suffered total mortality and the other showed a significantly lower final SH compared with the acclimated spat subgroups. These spat, which were 0.7 and 0.8 mm SH at deployment, belonged to the gill development stage 2 described by Beninger et al. (1994). The other spat in the study were stage 3 at transfer, further implying that the spat were transferred to the cold seawater conditions at a critical stage in life.

Since no significant difference in survival and final SH was found between the groups acclimated for 1 and 3 wk, we believe that 1 wk is sufficient for small scallop spat to adapt to 10°C. Adaptation of mussels to a change in temperature is shown by an immediate response in oxygen consumption and filtration rate, followed by a 2-wk acclimation period for physiological compensation to initial level (Bayne et al. 1976). The observed growth during the acclimation period for most groups (Fig. 6) confirms that 1 to 4 mm *P. maximus* spat can tolerate an abrupt change from 15°C to 10°C. Exposure to a decrease in temperature from 15°C to 5°C to 7°C, on the other hand, seemed to be too stressful for the small spat (0.7–2.6 mm). Compared with the survival (24%–60%) obtained for spat transferred to sea temperatures more equal to the hatchery temperature, the mean survival was low (<9%). A gradual exposure to cold water before deployment early in the season might be a better solution for adjusting the temperature tolerance limit for scallop spat. Laing (2000) successfully acclimated spat of 5 to 14 mm from a rearing temperature of 17°C to 5°C by temperature reduction rates of no more than 1°C per day. The constant and fluctuation temperature regime studied by Pilditch and Grant (1999) did not affect the shell growth rate of *P. magellanicus* differently, but limited ability to alter metabolic energy demands following temperature changes was shown. It is possible that *P. maximus* also has limited capability to regulate its metabolism to sudden changes of low temperatures. Thus, the success of spat production is highly dependent on deployment time, which was also shown for *P. magellanicus* (Grecian et al. 2000), and growth performance will depend on initial scallop vitality before abrupt transfer to colder water.

Temperature at deployment and the period of exposure to low temperatures are found to be the main factors affecting survival and growth for small *P. maximus* spat (1–5 mm) transferred from hatchery to sea conditions. Improvement of tolerance to cold water environment is shown by acclimation to lower temperature, leaving size at transfer a critical factor. From an economical point of view, the result was of limited interest, while the maximum mean survival did not exceed 9% for the smallest acclimated spat. To ensure high survival rates, spat of <2.6 mm SH should not be transferred to sea temperatures below 7°C. Alternatively, enhanced survival of spat transferred to temperatures from 5°C to 7°C may be achieved by deploying bigger spat (>4 mm). If the spat could be kept in the hatchery to approximately 4 mm and acclimated to a colder temperature, we believe that an earlier start of the growth season in early spring is possible.

ACKNOWLEDGMENTS

We would like to express our appreciation to Oygarden Scallop Hatchery for providing the spat and for placing their facilities at our disposal. Special thanks to the hatchery staff for technical assistance and to the Research Council of Norway who supported our work.

HETEROZYGOTE DEFICIENCIES AND GENOTYPE-DEPENDENT SPAWNING TIME IN *MYTILUS EDULIS*

MIGUEL A. DEL RIO-PORTILLA* AND ANDY R. BEAUMONT

School of Ocean Sciences, University of Wales, Bangor, Menai Bridge, Gwynedd, United Kingdom, LL59 5EY

ABSTRACT Deficiencies of heterozygotes against the expectations of the Hardy-Weinberg model are commonly observed in wild populations of marine bivalves and genotype-dependent spawning time has been proposed as a possible cause of heterozygote deficiency. Adult mussels, *Mytilus edulis* L., were collected every fortnight at two locations in the Menai Strait, North Wales during the spawning season in 1994 and induced to spawn artificially. Genetic analysis at ten allozyme loci revealed no significant differences in allele frequencies or heterozygosity between spawners and non-spawners during the season. It was concluded that the time that individual mussels spawned was not dependent on their genotype at these ten loci and could therefore not be an explanation for the significant heterozygote deficiencies observed at several loci in this study. The presence of null alleles and/or selection against heterozygotes was suggested as the most likely causes of heterozygote deficiency.

KEY WORDS: allozymes, heterozygote deficiency, *Mytilus edulis*, spawning time

INTRODUCTION

Deficiencies of heterozygotes against the expectations of the Hardy-Weinberg model are commonly reported in allozyme studies of bivalves (Gartney-Kepkay et al. 1980, Skibinski et al. 1983, Zouros & Foltz 1984, Gosling & Wilkins 1985, Volckaert & Zouros 1989, Beaumont 1991, Gosling 1992) and several explanations have been offered. The extensive larval dispersal exhibited by bivalves would tend to rule out the Wahlund effect (the result of sampling differentiated sub-populations or mixtures of cryptic species, Raymond et al. 1997) or inbreeding and, although null alleles certainly occur in some populations of bivalves (Gaffney 1994, Hoare & Beaumont 1995), they need to be present at unexpectedly high frequency to explain the observed levels of heterozygote deficiencies. There may be differential selection against heterozygotes during different life stages (Hu et al. 1993). Indeed, Beaumont (1991) has demonstrated the generation of heterozygote deficiencies at the post-larval stage in laboratory-reared mussels, presumably through selection against heterozygotes, but evidence for this is extremely difficult to detect in natural populations. One explanation proposed by Zouros and Foltz (1984) is that spawning within a population of bivalves may be genotype-dependent. If, for example, homozygotes for the common allele at a locus tend to spawn at a different time, say a few days before or a few days after other genotypes in the population, then panmixia is disrupted and a deficiency of heterozygotes will occur at that locus among the offspring. Gosling and Wilkins (1985) have also proposed "that in species which have an extended spawning period, within a single locality, the biochemical genotype of individuals may be important in regulating spawning synchrony". Ríos et al. (1996) record apparent differences in spawning time between individuals with different heterozygosities in a Mediterranean population of *Pecten jacobaeus* L. but the relationship between genotype and spawning time has yet to be tested in any other bivalve species.

Temperature and food supply are considered to be the most important factors controlling gametogenesis and spawning in *Mytilus edulis*, although there may be an interaction between these and other exogenous and endogenous factors (Seed & Suchanek 1992). Mussels may spawn following a variety of stimuli (Seed & Suchanek 1992), but only those mussels which have completed gametogenesis and are "ripe" will spawn as a result of an artificial stimulus. The objective of the study presented here was to detect any possible allozyme genetic differences between those *M. edulis* which would spawn and those which would not, throughout the spawning season, using artificial spawning induction as a ripeness indicator.

MATERIALS AND METHODS

Adults of *Mytilus edulis* were collected from a rocky shore at Gallows Point, near Beaumaris (53°15′N, 4°5′W), and by the island of Ynys Faelog, Menai Bridge (53°14′N, 4°9′W), North Wales (referred to as 'Beaumaris' and 'Menai Bridge', respectively). From January to June 1994, every fortnight during low tide, *ca.* 30 mussels were collected from these sites and brought into the School of Ocean Sciences (University of Wales, Bangor) laboratory and held at 6 ± 1°C in tanks with a continuous flow of sea water until spawning induction (Table 1). In mid-April 1994, samples were collected within three days of each other, but the samples from Menai Bridge were lost due to a technical failure in the holding tank. Usually spawning trials were attempted within three days of collection, but when trials were delayed for longer than three days, a mixture of the micro-algae *Pavlova lutheri* (Droop) Green, *Rhinomonas reticulata* (Lucas) Novarino, *Skeletonema costatum* (Greville) Cleve and *Tetraselmis chui* (Kylin) Butcher was drip-fed into the tanks as a food supplement. Trials were always conducted within 15 days of collection. Spawning was induced by the injection of 2 ml of 0.5 M KCl into the mantle cavity of individual mussels that were then left out of water for one hour. Each mussel was then placed into a 250-ml glass jar and covered with 0.2 μm filtered and UV light treated seawater (FSW), and left at 16°C undisturbed for 24 hours. For each mussel in the trial, the maximum linear dimension of the shell was measured to the nearest 0.1 mm and the individual was categorised as a male, a female or a non-spawner.

Samples of posterior adductor muscle and digestive gland were taken from each individual to be genetically analysed, placed together in a microtube and frozen at −75°C, until electrophoresis.

nsp = non-spawner; spa = spawner; se = standard error.

All individuals which spawned (up to a maximum of 13) and about 10 non-spawners from each trial were scored. Starch gel electrophoresis was performed for ten enzymatic systems: NADH-diaphorase (DIA, 1.6.2.2), esterase-D (ESD 3.1.1.1), glucose phosphate isomerase (GPI 5.3.1.9), glutathione reductase (GSR 1.6.4.2), inorganic pyrophosphatase (IPP 3.6.1.1), leucine amino peptidase (LAP 3.4.11.-), mannose-phosphate isomerase (MPI 5.3.1.8), octopine dehydrogenase (ODH 1.5.1.11), 6-phosphogluconic dehydrogenase (PGD 1.1.1.44), phospho- glucomutase (PGM 2.7.5.1). Gels stained for ESD, GPI and LAP were run in TME buffer (0.1 M Tris, 0.1 M maleic acid, 0.01 EDTA and 0.01 $MgCl_2$, pH 7.4). Gels stained for DIA, GSR and IPP were run using a 0.1 M Sodium Citrate pH 7.4 buffer gel and run in TME pH 7.4 electrode buffer. TME buffer at pH 6.0 was used for ODH and PGM gel and electrode buffers (Beaumont & Beveridge 1983, Gentili & Beaumont 1988). MPI was run as described by McDonald et al. (1991) together with PGD. LAP and ODH were stained as described by Beaumont et al. (1983), and Beaumont et al. (1980), respectively. Other enzymes were stained following Harris and Hopkinson's (1976) procedures, except that meldola blue was used instead of PMS (Turner & Hopkinson 1979). Allele nomenclature designated the commonest allele as '100' and the other alleles were given numbers according to their electrophoretic mobility relative to the 100 allele.

To test shell length against spawning time, two-factor ANOVA for mussel length was performed using the sampling date and whether or not the mussel spawned as the two factors analysed (Fry 1993). A few trials early and late in the spawning season produced fewer than four spawners and these trials were excluded from the analysis.

Spawners and non-spawners were considered as separated subpopulations. The data set was analysed using BIOSYS-1 (Swofford & Selander 1981) to calculate allele frequencies and unbiased heterozygosities (Nei 1978). Agreement with the Hardy-Weinberg (HW) model was tested using the exact test (Genepop: Raymond & Rousset 1995) and the direction of any deviation from the model was indicated by the sign of Wright's (1951) fixation index *Fis*. Mean unbiased individual heterozygosities were compared for each sample using the *t*-test (Sokal & Rohlf 1995). Chi-square contingency table analysis was used to determine whether there was any relationship between the frequency of a specific allele at a locus and spawning. This analysis considered Beaumaris or Menai Bridge as populations, and spawners and non-spawners as subpopulations within them. The sequential Bonferroni technique (Hochberg 1988) with an $\alpha = 0.05$ was used to establish whether a particular test was significant when considering multiple tests of the same hypothesis.

RESULTS

Between the 28th of January and the 12th of June 1994, a total of 658 mussels was subjected to spawning induction treatment and 235 spawned (Table 1). There were minor differences in the number of spawners from the Beaumaris (B) and Menai Bridge (MB) populations during the season. By the end of January the mussels were becoming sufficiently ripe to spawn following artificial induction. The number of spawners increased as the season progressed with a peak between mid March and the end of April. Spawning activity had ceased by the beginning of June.

The mean shell lengths of mussels used in these trials were between 57.2 and 66.2 for Beaumaris and between 56.6 and 65.0 mm for Menai Bridge (Table 1). Two-way ANOVAs for both sites showed no significant difference in mussel shell length between spawners and non-spawners for Menai Bridge ($F_{1,249} = 0.96$, ns),

spa = spawner, nsp = non-spawner, ns = not significant, * = significant following Bonferroni correction, — test not carried out due to presence of a fixed allele, s.e. standard error, *t* value of the difference between heterozygosities of spawners and non-spawners.

but a significant difference for Beaumaris ($F_{1,307} = 10.091$, $p = 0.001$), with spawners being smaller. Overall (considering both sites), the mean shell length of the spawners was larger than that of the non-spawners in 6 instances out of 18. This ratio was not significantly different from a 1:1 ratio ($p > 0.1$) using the sign test (Sokal & Rohlf 1995). No significant difference in mussel length between sampling dates was found in Beaumaris ($F_{9,307} = 1.88$, ns), whilst there was a difference in Menai Bridge ($F_{7,249} = 3.39$, $p = 0.002$); however, this difference was probably a sampling effect because mussels were only roughly size-selected during collection. There was no tendency for mussels of a particular size to spawn for each sampling date and at each site, because there was no significant interaction in any of the two-factor ANOVAs (B: $F_{9,307} = 1.71$, ns; MB: $F_{7,249} = 1.76$, ns).

Agreement with HW expectations (by exact test) was found at most loci in most samples, except in one out of 152 cases for Beaumaris (*Dia*, March 12 spawners). This value represents only 0.65% of the total number of tests of the Hardy-Weinberg. Also whenever *Fis* was significantly different from zero at a particular locus it was always positive (5 cases in Beaumaris and 1 in Menai Bridge, Table 2 and Table 3) indicating too few heterozygotes. In one case (March 12 non-spawners, Table 2) there was a significant positive value of *Fis* across all loci indicating a cumulative heterozygote deficit in this group of 10 mussels.

The mean unbiased heterozygosity (*H*) across loci ranged from 0.167 to 0.360 in Beaumaris and from 0.167 to 0.32 in Menai Bridge. There were no significant differences between the *H* of spawners and non-spawners in any trial for either population (10 tests for Beaumaris and 8 for Menai Bridge, Table 2 and Table 3).

The sign test was used to determine whether there was a difference between the number of negative and positive values of the *Fis*. Firstly, +*Fis* and −*Fis* values for spawners and non-spawners were separately added for all loci at each sampling date (column wise - given at foot of Table 2 and Table 3). It was not possible to say that there were significant differences in any case. Secondly, the *Fis* values were added horizontally for each locus between spawners and non-spawners in both sites (Del Rio-Portilla 1996). Not a single significant difference was found after Bonferroni adjustment. Finally, total *Fis* values were assessed, and the negative percentages were 44.1% for spawners and 51.6% for non-spawners in Beaumaris, whilst in Menai Bridge, the *Fis* + ve values were 43.8% and 37.2% for spawners and non-spawners, respectively. None of these was significantly different from 50%. Furthermore, Wilcoxon tests showed that no median of the *Fis* values was different from a value of zero (B: spawners C (Wilcoxon statistic) = 639, ns; non-spawners C = 705, ns; MB: spawners C = 509, ns; non-spawners C = 452, ns)

Chi-square contingency table analyses were carried out on allele frequency data at each locus for each trial date and for both sites. In no case was there a significant difference in allele fre-

spa = spawner, nsp = non-spawner, n = number of mussels scored for that particular locus, adjustment to HW model, ns = non significant, * significant after Bonferroni correction.

quencies between samples of spawners and non-spawners suggesting no relationship between the possession of a particular allele and likelihood of spawning following artificial stimulus (Del Rio-Portilla 1996).

Data from all spawners were pooled, as were data from non-spawners, for each sample site and genetic analyses are given in Table 4 and Table 5. These pooled data showed agreements with the Hardy-Weinberg model at most of the loci, except in *Dia*, and *Pgm* in both spawners and non-spawners from Beaumaris, and *Pgm* of spawners in Menai Bridge. As with the unpooled data *Fis* was positive in all these cases of significant deviation from the model. Overall, the number of loci with positive values of *Fis* was 24 out of 40 tests which is not significantly different from a 1:1 ratio.

Heterozygosity was 0.23 (s.e. 0.061) and 0.26 (s.e. 0.063) for spawners and non-spawners in Beaumaris, and 0.26 (s.e. 0.070)

and 0.24 (s.e. 0.065) for spawners and non-spawners in Menai Bridge respectively. Neither of these differences between spawners and non-spawners was significant ($t = -0.353$, ns and $t = 0.038$, ns for Beaumaris and Menai Bridge respectively).

DISCUSSION

Artificial induction of spawning in the laboratory is currently the best test we can make of the ripeness of mussels in the wild. It could be argued that if one mussel (A) spawns in the laboratory following an artificial stimulus while another (B) does not, this does not prove that mussel A would spawn, and mussel B would not spawn, following a natural stimulus in the wild, however, there are no published reports of attempts to detect spawning mussels *in situ* and the practical problems associated with detecting, and collecting spawning individuals of bivalves in the wild for a study such as this are probably insurmountable. It is worth noting that in our trials the results of artificial mussel spawning induction during the spring agreed with previous observations of spawning in the wild in the Menai Strait (Bayne 1963; Seed 1976), with mussels having both an artificially induced and a natural spawning peak between April and May.

The data overall show a trend for mussels which spawned to be smaller than those which did not spawn and this effect is significant in the Beaumaris population. Possibly smaller mussels are more sensitive to the spawning stimulus but, more likely, this is a gender effect. Almost invariably more males than females spawn following the stimulus and this is particularly noticeable early in the season (Del Rio-Portilla 1996). Because of the reduced unit energetic cost of male vs. female gametes, males may spawn at a smaller size than females and this could account for the difference in size between spawners and non-spawners if we assume a 1:1 sex ratio in the sampled population.

Our results provide no evidence to support the hypothesis proposed by Zouros and Foltz (1984) that heterozygote deficiencies in natural populations of bivalves might be caused by genotype-dependent spawning. Allele frequencies at the scored loci were not different between spawning and non-spawning groups. Furthermore, average heterozygosities across all loci did not differ between groups and neither did an individual mussel's heterozygosity (the number of the scored loci at which it was heterozygous) relate to whether or not it spawned (Del Rio-Portilla 1996).

This is of interest because, according to Rodhouse et al. (1986), reproductive output (the number of gametes released) is related to individual heterozygosity in adult mussels larger than 49 mm and highly heterozygous mussels should therefore produce more offspring.

The overall samples from the Menai Bridge and Beaumaris populations do exhibit a similar pattern of heterozygote deficiencies to previous studies with other populations of mussels and with other species (Gosling & Wilkins 1985, Gaffney 1990). Although there were not significantly more instances of negative than positive values of *Fis*, and three of the four mean values of *Fis* were not significatively different from zero (Beaumaris: spawners mean 0.112 s.e. 0.036, $p < 0.01$; nonspawners mean 0.067 s.e. 0.028 n.s.; Menai Bridge: spawners mean 0.076 s.e. 0.040 n.s.; nonspawners mean 0.069 s.e. 0.034 n.s.), whenever significant deviations from the Hardy-Weinberg model did occur, they were always the result of too few heterozygotes. The loci showing heterozygote deficiencies in this study (based on exact test of H-W or significance of *Fis*, Tables 4 and 5 : *Dia, Pgd, Odh* and *Pgm*) have also shown heterozygote deficiencies in previous studies of mussels and other bivalves (Volckaert & Zouros 1989; Fairbrother & Beaumont 1993; Gaffney 1994; Hoare & Beaumont 1995; Ríos et al. 1996).

Although our results have demonstrated that the heterozygote deficiencies in these mussel populations have not arisen as a result of the timing of spawning being genotype-dependent, we have not proven that they are caused by any other factor. The presence of a differentiated sub-population structure (Wahlund effect), or consistent mating between close relatives (inbreeding) within our sampled populations seem very remote possibilities. More likely is the miscoring of null-allele heterozygotes as homozygotes. There is evidence that juvenile mussels which are heterozygous, or even homozygous for a null allele at the *Odh* locus are able to survive and are apparently at no disadvantage compared with other genotypes possessing active *Odh* alleles (Hoare & Beaumont 1995) and null alleles have been found at other loci in laboratory crosses of mussels and other bivalves (Foltz 1986a & Foltz 1986b; Gaffney 1994; Del Río & Beaumont, 2000). However, the *Odh* locus is probably a special case because this enzyme operates in a biochemical pathway which may not be essential to the organism (Hoare & Beaumont 1995). Although null alleles may have caused the observed significant heterozygote deficiencies at the *Odh* locus in this study, null alleles are thought less likely to be present at sufficiently high frequency to account for the significant deviations from the Hardy-Weinberg model at other loci such as *Pgm* and *Pgd* which operate within critical biochemical pathways (Zouros & Foltz 1984). All four sub-samples of mussels (spawners and non-spawners at 2 sites, Tables 4 and 5) showed high positive values of *Fis* for the *Odh* locus (mean *Fis* = 0.184) which would be expected if null alleles were present in the populations. This was also true for the *Pgm* and *Dia* loci (mean *Fis* = 0.274 and 0.292 respectively), but not for the *Pgd* locus which had negative values of *Fis* in three sub-samples.

Finally, selection against heterozygotes should also be considered as a potential cause of the heterozygote deficiencies. If selection is operating at a locus we would expect it to have a similar force and direction in our four sub-samples of mussels and this is true for *Odh, Pgm* and *Dia* loci which all have large positive *Fis* values, but not for the *Pgd* locus.

We conclude that the heterozygote deficiencies against the Hardy-Weinberg model detected in this study are probably the result of the presence of null alleles and/or selection against heterozygotes, but that they are not caused by genotype-dependent spawning time.

ARTIFICIAL ENVIRONMENTAL CONDITIONS CAN AFFECT ALLOZYME GENETIC STRUCTURE OF THE MARINE GASTROPOD *PATELLA CAERULEA*

ANNAMARIA MAURO, NICOLO' PARRINELLO, AND MARCO ACRULEO*
Dipartimento di Biologia Animale via Archirafi 18, 90123 Palermo, Italy

ABSTRACT Samples of the Mediterranean limpet *Patella caerulea* collected from 10 sites were examined for genetic population structure. Six of the 20 identified enzymatic loci were polymorphic. The *AAT** locus was polymorphic only in two samples from an artificial environment (TI2 and PE). The proportion of polymorphic loci ranged from 0.20 to 0.30, and the observed and expected mean heterozygosity varied between 0.098 and 0.076 and between 0.109 and 0.086, respectively. Mean *Fis* values were significantly positive in *AAT**, ESTD *, *PEPC-2**, and *PEPD* , showing heterozygosity deficiency. In all, mean *Fst* value of 0.007 indicated high genetic homogeneity between the samples analyzed, whereas single-locus *Fst* analysis showed an interesting case of significant microscale genetic heterogeneity in *AAT** (*Fst* = 0.158, $P < 0.001$). The specimens collected from the two artificial environments (TI2 and PE) were responsible for *AAT** heterogeneity. These results, as suggested by other authors, could be related to the hydrodynamic conditions of artificial environments.

KEY WORDS: *Patella caerulea*, genetic variation, allozymes, artificial environment, Mediterranean Sea

INTRODUCTION

Patella caerulea L. is a very common gastropod along sheltered Mediterranean rocky shores, where it coexists with the congeneric species *P. rustica* L. and *P. ulyssiponensis* Gmelin. The Mediterranean sedentary *P. caerulea* presents a planktonic larval stage of uncertain length (Dodd 1957) and a high morphological variability (Bacci and Sella 1970, Sella et al. 1993) so that in some localities, shell coloration and morphology are very similar to those of *P. ulyssiponensis*.

The aim of the present paper is to analyze the genetic population structure of Mediterranean *P. caerulea* populations and also to compare natural and artificial samples to understand if allozyme polymorphism could be related to particular environmental conditions. Although some allozyme variation can be due to random genetic drift, good examples exist of natural selection acting on allozyme diversity. Allozyme heterozygosity and growth rate have been correlated in many molluses, even though the phenomenon is not universal (Volkaert & Zouros 1989) and natural selection acting on particular loci has been demonstrated in different organisms (Koehn et al. 1980, Hilbish et al. 1982, Altukhov 1990, Powers et al. 1991, Riddoch, 1993, Johannesson et al. 1995). Moreover, several authors (Karl & Avise 1992, Pogson & Zouros 1994) have compared different markers to analyze population genetic structure and have concluded that in some cases, allozyme diversity was dependent on natural selection.

MATERIALS AND METHODS

A total of 506 *P. caerulea* specimens was collected from the intertidal zone at eight sampling sites: Trieste (TR), Augusta (AU),

Scoglitti (SC), Capo Gallo (CG), Termini Imerese (TI1), Capo d'Orlando (CO), Ustica Island (UI), and Gaeta (GA). Two additional samples were collected from artificial environments: (i) a channel carrying discharge waters from the thermoelectric plant at Termini Imerese (TI2); and (ii) a tank collecting sea water to be directed to an aquaculture plant in Petrosino (PE; Fig. 1). Both tanks, 60 m^2 in volume and 2 m in depth, were above ground and were exposed to direct sunlight. Living specimens were transported in sea water to the laboratory where they were stored at −80°C until they were used for electrophoresis. The whole animal body was homogenized in distilled water, centrifuged at 25,000 *g* for 30 min, and the supernatant was used for electrophoresis. Details of polyacrylamide gel slab electrophoresis (PAGE) are given in Davis (1964). Locus and allelic nomenclature were according to Shaklee et al. (1990; Table 1). Buffer and staining procedures were adapted from Richardson et al. (1986). Genetic variation was es-

timated by calculating the percentage of polymorphism (0.99 criterion), the mean number of alleles per locus, and the observed and expected heterozygosity using the program GENEPOP (v. 1.2, Raymond & Rousset 1995). This program was also used to test for departure from Hardy-Weinberg equilibrium by the Markov chain method (Guo & Thompson 1992). The FSTAT program (v. 1.2, Goudet 1995) was used to calculate Weir and Cockerham's (1984) unbiased estimate of Wright's (1978) *F* statistics by means of permutational procedures to test for significance. Population pairwise comparisons for *AAT** locus were tested for heterogeneity of genotype distribution using GENEPOP, which calculates an unbiased estimation of the *P* value of a log-likelihood (G) based on exact test by the Markov chain method (Goudet 1995).

RESULTS

Twelve enzymatic systems were analyzed and 20 loci were scored (Table 1). Among them, six were polymorphic under the 0.99 criterion: *AAT**, *EST-D**, *PEPC-2**, *PEPD** *PGI**, and *SOD-1** (Table 2). Sample size, allelic frequencies, and observed and expected heterozygosities for each polymorphic locus are given in Table 2. Four loci (*ESTD**, *PEPC-2**, *PEPD**, and *PGI**) were polymorphic in each sample analyzed. *SOD-1** was polymorphic in the TR, AU, and TI2 samples. Artificial environments (TI2 and PE) showed an additional polymorphic locus, *AAT**, which occurred within two alleles (**100* and **115*, Table 2). The mean number of alleles per locus ranged from 1.5 in CO to 2.0 in TI2, while the proportion of polymorphic loci ranged from 0.20 in SC to 0.30 in TI2. The mean observed heterozygosity ranged from 0.098 (TI2) to 0.076 (UI), and the expected heterozygosity ranged from 0.109 to 0.086. Three loci showed a significant genotype frequency departure from *H-W* expectations: *AAT** in PE, *ESTD** in GA, and *PEPC** in PE. The corresponding fixation index (*Fis*) was significantly positive, showing a heterozygote deficiency (Table 2). Moreover, single-locus *Fis* averaged over all the samples was significantly positive in *AAT**, *ESTD**, *PEPC**, and *PEPD** loci, and *Fit* was significantly positive in *AAT**, *PEPC**, and *PEPD** (Table 3).

To examine the spatial distribution of allelic frequencies, the mean value of *Fst* was calculated among the sampled sites. In all, a genetic homogeneity was indicated by the 0.007 value. On the contrary, single-locus *Fst* revealed a significant heterogeneity in *SOD** (*Fst* = 0.021, $P < 0.05$) and a highly significant heterogeneity in the *AAT** locus (*Fst* = 0.158, $P < 0.001$; Table 3). The high value of *Fst* in the *AAT** locus was dependent on artificial samples as shown in *Fst* comparison between all population pairs (Table 4). The genetic heterogeneity in *AAT** locus was high in all natural vs. artificial comparisons, whereas genotype distribution was homogeneous between the artificial environments (TI2 and PE).

*PGI**	−0.034	−0.004
*SOD-1**	−0.023	0.021
Mean	0.106*	0.007

* $P < 0.05$.

DISCUSSION

The genetic parameters reported in this study have different values with respect to those observed by Sella et al. (1993) for the same species collected from the Ligurian coast (Fig. 1). We have found similar mean number of alleles per locus, but smaller values of polymorphism and mean heterozygosity. These differences could be attributed either to the different electrophoretic systems used (polyacrylamide vs. starch) or to the higher number and different kind of loci analysed by us.

With regards to heterozygosity, the observed deficiency at different loci and in different populations is consistent with the data reported by Zouros and Foltz (1984) for several mollusc species. Different mechanisms could explain heterozygosity deficiency such as inbreeding, Wahlund effect, selective mortality of certain genotypes, and null alleles (Volckaert & Zouros 1989, Manuris et al. 1998). Inbreeding is a populational event and thus, should it be responsible for the heterozygote deficiency, we would observe the effect across all polymorphic loci. However, as some loci showed a negative value of F_{IS} (i.e., heterozygosity excess) and as no homozygotes for null alleles were observed, we can reject the above explanations as responsible for causing heterozygosity deficiency. We cannot discard the Wahlund effect hypothesis, since heterozygosity deficiency could be the result of localized population mixing with allelic frequency differences in some loci. Finally, it cannot be excluded that locus-specific selection may cause heterozygosity deficiency for some loci and not for others.

The mean F_{ST} value was very low (0.007, $P > 0.05$) and was comparable to those obtained by Badino et al. (1986), who found F_{ST} values lower than 0.01 in Thyrrenian and Adriatic *P. caerulea* populations (Fig. 1). This suggests that there is a high level of gene flow among different geographic areas and that *P. caerulea* population size is very large. Despite the sedentary adult stage supposed to favor genetic differentiation, the larval stage increases gene flow and could be responsible for the observed large-scale genetic homogeneity. In contrast, single locus F_{ST} analysis showed significant heterogeneity in *SOD-1** (F_{ST} = 0.021, $P < 0.05$) and highly significant heterogeneity in *AAT** (F_{ST} = 0.158, $P < 0.001$). Whereas *SOD-1** heterogeneity was caused by two rare alleles (**90* and **115*) and could be related to geographical distance, the highly significant F_{ST} value found in *AAT** revealed an interesting case of microscale genetic heterogeneity.

The *AAT** locus occurred as a single allele (**100*) in natural environments, but showed two alleles (**100* and **115*) in the samples taken from the two artificial basins (PE and TI2; Table 2). The **100* allele was the same found by Sella et al. (1993), whereas Badino et al. (1986) did not analyze the *AAT** locus. It is relevant that *AAT** allelic frequencies were very similar between TI2 and PE samples (sites about 150 km apart), whereas genetic heterogeneity was maintained even if the distance between samples did not exceed 1 km (TI1-natural vs. TI2-artificial, Table 4). Hence, despite the large-scale genetic homogeneity observed for the majority of polymorphic loci analyzed, the *AAT** locus showed a very highly localized heterogeneity. Significant heterogeneity among populations on a local scale, but little additional large-scale geographical variation, have been observed in several marine gastropods molluscs (Johnson & Black 1984, Johnson et al. 1993, Hurst & Skibinski 1995), and different mechanisms such as mixing of larvae or post-settlement selection have been invoked. As we found a high level of homogeneity at the majority of polymorphic

loci, the reproductive isolation between coast and artificial environments as an explanation for the spatial differentiation in the *AAT** locus can be rejected. The inconsistency among the loci analyzed indicates that the cause for local heterogeneity is not dependent on breeding systems, but is locus specific.

As several authors suggest, allozymes do not always behave as neutral markers (Hilbish et al. 1982, Altukov 1990, Karl & Avise 1992, Riddoch 1993, Johannesson et al. 1995, Mitton 1997) and even though we were not able to demonstrate the functional relationship between allozyme variations and environmental parameters of artificial basins, we think that the strong genetic heterogeneity found in the *AAT** locus may be related to the peculiar environmental conditions. The first artificial sample site was the channel collecting the discharge water used to cool down the Termini Imerese thermoelectric plant (TI2). Salinity of the discharged water equals that of sea water (37‰), whereas temperatures are slightly higher (1°C to 2°C) than those measured in surrounding coastal waters. Hydrodynamic patterns are remarkably different as the site is sheltered from wave motion, though it is subjected to a continuous flow of discharge water. The second artificial site, located in an aquaculture plant in Petrosino (PE), is a tank collecting sea water to be directed to the breeding tanks. As result of the continuous exchange with the seawater, temperature and salinity do not differ much when compared to the natural sites, whereas the hydrodynamic patterns do, owing to the continuous flow of incoming water. Even if several authors invoked temperature (Powers et al. 1991, Sokolova & Portner 2001) and salinity (Koehn et al. 1980) as responsible for the particular genetic adaptation found in marine organisms, we cannot demonstrate this tendency because in our case study, temperature and salinity of artificial sample sites are the same of those of the sea. Microscale allozyme variation in the *AAT** locus was also found in the marine snail *Littorina saxatilis* (Johannesson et al. 1995), and the authors concluded that a strong natural selection was acting. Therefore, it is probable that the *AAT** locus was the specific target of complex environmental-genetic interactions. The *115** allele was probably maintained at low frequencies (below the limit of detection in a sample of 50–100 individuals) in natural environments by a mutation/selection balance, and it increases in frequency as a result of selection in artificial environments. Unfortunately, we do not know what kind of physiological consequences a locus could have. The *AAT** enzyme is involved in the degradation process of nitrogen-containing compounds and it is known that marine molluscs of the intertidal zone have developed different mechanisms of excretion of these compounds in relation to vertical zoning and to wave action exposure (Cognetti & Sarà 1981). The microscale variation in the *AAT** locus found in *P. caerulea* and in *L. saxatilis* could be related to some of these adaptive processes.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. Marco Costantini (Riserva marina di Miramare, Trieste) for the collection of Trieste samples. Research was supported by MURST (40% and 60%).

EVALUATION OF MICROSATELLITE PRIMER CONSERVATION IN ABALONE

BRAD EVANS,[1,2,3]* N. CONOD,[1] AND N. G. ELLIOTT[1]

[1]CSIRO Marine Research, GPO Box 1538 Hobart, Tasmania 7001, Australia; [2]School of Zoology, University of Tasmania, GPO Box 252-05, Hobart, Tasmania 7001, Australia; [3]Aquaculture CRC Ltd. PO Box 123, Broadway, NSW 2007, Australia

ABSTRACT This study investigated the interspecific amplification of 22 microsatellite loci developed for *Haliotis rubra* across 12 other species within the Haliotidae. We reveal, through the discussion of three specific cases, a need for more thorough assays of microsatellite locus conservation, to ensure the utility of existing markers in foreign species. Optimization and analysis of PCR products revealed that of 12 loci examined in the Australian *H. laevigata*, only five were able to be reliably scored, while 6 of 10 for the South African *H. midae* were scoreable and none of the three for the North American species were useable. The assay examines five species from Australia, three from New Zealand, two from South Africa and two from North America. Amplification success varied from 68% for *H. conicopora*, a possible sub-species, to 14% for the distantly separated and related species from North America. The importance of cross-species amplification is discussed, but it is apparent that the proportion of markers that may be useful in other species of the same genera will vary greatly with the taxa being investigated.

KEY WORDS: *Haliotis*, abalone, microsatellites, aquaculture, primer conservation

INTRODUCTION

Members of the genus *Haliotis*, commonly called abalone, are distributed in coastal waters of all continents. Many of the 57 recognized species (Geiger 2000) are harvested commercially or recreationally, and they are a highly valuable marine resource. Abalone populations, like those of most highly prized marine resources, have come under increased legal and illegal harvesting pressures in recent years as demand for the product continues to rise, and methods for their capture and distribution are refined. Along with the expanding effort within abalone fisheries worldwide, and in some cases the decline of those fisheries, there has been extensive development in the culture of many abalone species (Oakes & Ponte 1996, McBride 1998, Cook 1998). An important technological advancement that will benefit both the culture and wild harvest industries is the development and application of molecular genetic markers.

Molecular genetic markers are widely used in many seafood industries for both wild and aquaculture needs; for example, in Salmonids (Reilly et al. 1999) and oysters (McGoldrick & Hedgecock 1996). They can be used for applications as diverse as tracking the biological history of populations (Chambers & MacAvoy 2000), or as specific as determining the parentage of individuals in culture (O'Reilly et al. 1998). One such marker that has been applied in other genera (Dallimer 1999, Wu et al. 1999, Nesje et al. 2000) but has only recently become popular in abalone research is microsatellite DNA. This marker consists of a nucleotide sequence of between two and six base pairs repeated in series at a set point on a chromosome (locus). The number of times that sequence is repeated at a single locus varies within (heterozygous individuals) and between individuals (intra-specific variation), and where that same locus is conserved across species, the number of repeats may vary widely (inter-specific variation) (Wright & Bentzen 1994).

Microsatellite markers have been developed from partial genomic libraries of four *Haliotis* species: *H. asinina* (Selvamani et al. 2000), *H. kamtschatkana* (Whithler, pers. comm.), *H. rubra* (Huang & Hanna 1998, Evans et al. 2000) and *H. rufescens* (Kirby et al. 1998). The development of microsatellite DNA markers, as described in each of these papers, is a time consuming and expensive process (Wright & Bentzen 1994). For these reasons, the efficacy of markers between species within the same genus or family have been examined in both plant and animal groups with ambiguous results (Dowling et al. 1996, Huang & Hanna 1998).

White and Powell (1997) tested 11 microsatellite markers developed for the hardwood, *Swietenia humilus* for conservation within 11 members of the Meliaceae family, representing seven genera. They detailed four species specific, one genus specific and three family wide markers. This trend of good marker conservation within plant families is supported by other studies such as that by Thomas and Scott (1993) who found that primer sequence conservation existed among grapevine species, and more recently by Rosetto et al. (2000) who showed similar sequence conservation among members of the Myrtaceae family.

Wirth et al. (1999) examined conservation of 11 microsatellite loci developed for the Walleye, *Stizostedion vitreum* in four species representing two genera of the Percidae family. Three of the markers were conserved in all species tested, two were found to be specific to *Stizostedion* genus, four produced amplification from both genera, but not all species within them, and the remaining two markers amplified only in *S. canadese*. Primer sequences have also shown some conservation across 10 species of four genera of Lemur, endemic to Madagascar (Jekielek & Strobek 1999).

Huang and Hanna (1998) considered the cross-species amplification of their three *H. rubra* microsatellite loci in species from USA (2 species), South Africa (2 species), South Korea (6 species) and Australia (5 species). Of the ten species tested from outside of Australia, only two of the South Korean species produced any amplification product. Within Australian species the markers were more conserved, with at least two of the three loci producing an amplification product in all Australian species tested, except for *Haliotis laevigata*, the greenlip abalone, which failed to amplify a product at any of the three loci. As *H. rubra* and *H. laevigata* are known to produce hybrids in the wild (Brown 1995) this latter result is unexpected, and required further examination as the hybrid is being developed as an aquaculture product for which molecular markers are required.

In this article we describe the cross-species amplification of 21 microsatellite loci (22 primer pairs) developed for use in the Aus-

*Corresponding author. E-mail: Brad.Evans@marine.csiro.au

tralian Blacklip abalone, *Haliotis rubra* (Leach, 1814). Twelve species from Australia (5 species), New Zealand (3 species), South Africa (2 species) and North America (2 species) were tested. These 12 species come from two diserete phylogenetic clusters within the genus based on sperm lysin DNA sequences (Lee & Vacquier 1995). We then expand upon this work by describing the optimization of some of these loci for genetic variation research in wild and cultured South African *Haliotis midae*, pedigree analysis and genetic variation research with the Australian *H. laevigata*, and genetic variation studies in the North American abalone, *H. fulgens*.

MATERIALS AND METHODS

Microsatellite Amplification

The twelve abalone species tested in this study were chosen to provide both close and distant evolutionary relationships to *Haliotis rubra*. Four species (*H. conicopora* Péron, 1816; *H. laevigata* Donovan, 1808; *H. roei* Gray, 1826; *H. scalaris* Leach, 1814) share a temperate Australian habitat with *H. rubra*, while *H. asinina* (Linnaeus, 1758) is a tropical species form Australian waters. *Haliotis australis* (Gmelin, 1791), *H. iris* (Gmelin, 1791) and *H. virginea* (Gmelin, 1791) are temperate species from neighboring New Zealand. The two most prevalent South African species *H. midae* (linnaeus, 1758) and *H. spadicea* (Donovan, 1808) and two species of commercial importance in North America *H. corrugata* (Wood, 1828) and *H. fulgens* (Philipi, 1845) are examples of distant temperate species.

Twenty-two microsatellite primer pairs were developed for *Haliotis rubra* (Table 1) using methods described in Evans et al. (2000). Their potential for cross-species amplification was tested under standard PCR conditions with DNA extracted from gill or muscle tissue from at least two individuals of the 12 test species using a modified CTAB protocol (Grewe et al. 1993). Such low sample sizes are a problem for determination of diversity indices or population structure, but are sufficient for the detection of the locus in another species.

TABLE 1.

Characterization of 22 microsatellite primer pairs tested for cross-species amplification in this study. Previously published primers appear last, and a citation is given instead of full sequence.

The two primer pairs preceeded by the "*" both amplify the same locus, with *cmrHr*2.9 being internal to *cmrHr*2.15.

PCR reactions were performed in a volume of 25 µl consisting of 67 mM TrisHCl, pH 8.8; 16.6 mM $(NH_4)_2SO_4$; 0.45% Triton X-100; 0.2 mg/mL gelatin; 2.5 mM $MgCl_2$; 10 pmoles of each primer; 200 µM dNTPs; 0.5 U *Taq* F1 polymerase (Fisher Biotech); and ~ 20 ng genomic DNA template. Amplification was in a Perkin Elmer 9600 thermocycler with one cycle of 94 C for 1 min, 50 C for 15 s and 72 C for 1 min, followed by 30 cycles of 94 C for 15 s, 50 C for 15 s and 72 C for 1 min. These cycles were followed by a final extension step of 72 C for 10 min. Amplification products were visualized on 2% TBE agarose gels, and markers were scored as present when a single band of between 75 bp and 450 bp was detected (Table 2). Any amplification products above this size range, although possibly containing the microsatellite repeat unit, can not be scored on the ABI377 using the size standards commonly available. It is possible to score larger alleles with different systems, but such large products increase the possibility of mutation in the regions flanking the microsatellite rather than within the repeat unit. In such cases it would be best to design new primers closer to the repeat unit. Amplification products less than 75 base pairs in size are difficult to reliably score due to their proximity to such PCR artifacts as primer-dimer, and the presence of unincorporated dyes.

H. midae *Optimization*

The loci that produced an amplification product for *H. midae* under standard conditions were further examined to optimize PCR parameters. Samples were initially subjected to PCR amplification at temperatures of 50 C and 55 C and with DNA template concentrations of 10ng/µl and 2ng/µl. Amplification products for all ten markers were not improved by increasing the annealing temperature from 50 C to 55 C, but were improved by increasing the DNA template concentration to 10ng/µl in all samples. The markers were amplified in eight individuals of *H. midae* from Cape Hangklip on the southwest coast of South Africa. Products were diluted relative to amplification strength and mixed with formamide, loading dye and Genescan Tamra500 size standard (PE-Applied Biosystems), denatured at 95°C for 2 min and 1.2µl loaded onto a 4% denaturing polyacrylamide gel. Samples were run on an ABI377 DNA autosequencer and genotypes determined using Genpotyper® software. Allele variation was scored between the eight individuals.

H. laevigata *and* H. fulgens *Optimization*

All loci that produced an amplification product in one of these two species under standard amplification conditions were subjected to further testing for optimization. This included a range of annealing temperatures from 48°C to 58°C, "Touchdown-PCR" to improve primer specificity, where the annealing temperature at the beginning of the cycling program was high and was lowered by either 0.5 or 1.0°C each cycle until the lowest selected annealing temperature was reached. In addition, DNA template concentrations tested ranged from 1ng/µl to 30ng/µl, and $MgCl_2$ concentrations tested ranged from 1mM to 5mM. All loci were tested on at least 30 *H. laevigata* or 8 *H. fulgens* individuals.

RESULTS

Microsatellite Amplification

Nineteen of the twenty-two primer pairs tested successfully amplified a product in at least one species other than *H. rubra* (Table 2). Not surprisingly, the species that appears to have retained the most loci, at 15, is *H. conicopora*, a species that has been touted as perhaps a sub-species of *H. rubra* (Geiger, 2000). The three other temperate Australian species (*H. laevigata*, *H. scalaris*, *H. roei*) produced an amplification product from twelve of the 22 primer pairs. *Haliotis asinina*, the only tropical species included in the study showed sequence conservation in only five of the markers tested. The three species from New Zealand showed conservation of 5, 5, and 9 markers for *H. iris*, *H. australis* and *H. virginea* respectively. As expected there was little cross-species amplification seen in the North American species *H. rufescens* and *H. fulgens* (three markers each), which were shown to be in a distant clade to *H. rubra* by Lee and Vacquier (1995). It should be noted that the three loci producing an amplification product in the two North American species were the only loci to amplify a product in all 12 species tested. Interestingly though, the South African species showed more sequence conservation than the species from New Zealand, with ten markers being conserved in *H. midae* and nine in *H. spadicea*. None of the primer pairs was shown to be specific to all Australian species or to particular climatic regimes such as temperate and tropical species. Some primer pairs produced an amplification product that was dramatically different in size to that expected. Where that product was greater than 450 or less than 75 base pairs the marker was denoted by an "a" for altered product size. Although these altered products may contain the same microsatellite as other amplification products, they can be of no use if they can't be scored reliably.

Previously, researchers have simply reported agarose gel detection as the retention of a locus in a related species. In this article, we attempt to bridge the gap between identifying the presence of a marker in a related species, and the use of that marker for further research. We present here, three case studies, in which we have taken the markers identified from the preliminary screening tests and attempted to optimize them for routine research in *Haliotis midae*, *H. laevigata*, and *H. fulgens*.

Haliotis midae—*the South African Abalone*

The 10 loci shown to produce an amplification product from *H. midae* in the preliminary screening were: *cmrHr*1.23, *cmrHr*1.24, *cmrHr*2.9, *cmrHr*2.15, *cmrHr*2.20, *cmrHr*2.23, *cmrHr*2.27, *cmrHr*2.29, *cmrHr*2.30, *cmrHr*2.36 (Table 2). At the initial PCR amplification conditions, both *cmrHr*2.27 and *cmrHr*2.30 produced non-specific products when examined using the more sensitive automated detection techniques. These loci were re-amplified at annealing temperatures of between 50C and 58C and with $[MgCl_2]$ of between 2.0 and 3.0 mM. The resultant amplification products however were also non-specific and these markers were not examined further.

Two of the markers were monomorphic in the eight individuals examined and were not tested further in this study. These markers were *cmrHr*1.24 and *cmrHr*2.27. It is unlikely that these markers are actually the same locus as that amplified in *H. rubra*, as they were somewhat smaller than the product produced in that species, and did not show characteristic microsatellite amplification profiles. The variation at each of the remaining 6 loci ranged from the minimum of 2 alleles at *cmrHr*2.30 (226–242 bp), 3 alleles at *cmrHr*2.23 (244–252 bp), 4 alleles at *cmrHr*2.36 (101–119 bp), 5 alleles at *cmrHr*2.15 (250–280 bp), 6 alleles at *cmrHr*2.9 (173–205 bp) and a maximum of 8 alleles at *cmrHr*2.29 (425–469 bp).

Assays producing a PCR product of expected size are indicated by +, those producing multiple bands or no product as –, and those producing bands of an altered size to that expected are represented by an "a".

Haliotis laevigata—*the Greenlip Abalone*

Of the 12 markers identified as being conserved in *H. laevigata* (Table 2), only five proved to be reliable for further studies after evaluation in 20 greenlip individuals. The reasons for exclusion of the other seven markers are listed in Table 3, but were due to either non-specific or unreliable amplification. Touchdown PCR cycles failed to clean up the peak profiles of locus *cmrHr*2.22. Two loci, *cmrHr*1.6 and *cmrHr*1.24 were monomorphic at 81 and 228 bp respectively in the 12 individuals examined, while the remaining three loci were variable with 7, 6 and 7 alleles detected for *cmrHr*2.14, *cmrHr*2.23 and *cmrHr*2.30 respectively.

Haliotis fulgens—*the Blue Abalone from Mexico*

The preliminary screening process identified three markers that produced an amplification product. These markers were *cmrHr*2.3, *cmrHr*2.20 and *cmrHr*2.27 (Table 2). PCR amplification products were however, always non-specific when visualized on agarose gels after all optimization conditions. Each product consisted of multiple bands within a small size range, such that allele identification was unreliable.

DISCUSSION

The development of microsatellite markers is known to be both expensive and time consuming (Wright & Bentzen, 1994). Many researchers that have produced microsatellite markers for their species have therefore examined the applicability of those markers to similar questions in related species. The use of agarose gel detection of PCR products has been utilized for the estimation of microsatellite loci conservation across species by researchers of other taxa (White & Powell 1997, Isagi et al. 1999). Huang and Hanna (1998), Wirth et al. (1999) and Rossetto et al. (2000), however examined these products further by denaturing polyacrylamide gel electrophoresis (PAGE) methods which reveal allele sizes and genotypes. Others have sequenced the markers in the new species to ensure that the locus being amplified does indeed match that expected (Ezenwa et al. 1998).

Whilst the screening of microsatellite markers in related species by sequencing techniques is obviously the most thorough method to determine marker conservation, it is also very expensive and time consuming. In instances where large numbers of microsatellite markers are being screened across many related species for which markers are not immediately required, this process may be considered to be excessive. Likewise, the optimization of primer pairs for genotyping through either radioactive labels or fluorescence primed, automated detection techniques is also time consuming and expensive. For this reason we took the simplest approach to determining marker conservation within abalone and have then followed this by detailing efforts to optimize the markers identified in the preliminary screening for use in other species.

Our research shows that a simplistic approach such as our initial screening can lead to a misleadingly high number of markers appearing to be conserved in related species. We report a 60% (6 from 10) success rate in the optimization of *H. rubra* markers for *H. midae*, 25% (3 from 12) for *H. laevigata* and 0% (0 from 3) in *H. fulgens*. Whilst the testing of molecular markers in related species is an important component in the sharing of information, it should be noted that simply determining that a product of similar size can be amplified in another species does not suggest that marker will be useful for that species. The three markers suitable for further studies of *H. laevigata* were *cmrHr*2.14, *cmrHr*2.23 and

TABLE 3.

Microsatellite markers initially identified as conserved in *H. laevigata*, and reasons for their exclusion from further research.

Locus	Accession numbers	Repeat Sequence	Reasons for exclusion
*cmrHr*1.6	AF 302828	$(CA)_4$ $(CA)_3$	**Monomorhic in H. laevigata**

Sample size for testing was n = 12.

*cmrHr*2.30. Two of these three markers have been used to determine broodstock contributors in controlled spawning of *H. laevigata*/*H. rubra* hybrids at a commercial culture facility (unpublished data). Locus *cmrHr*2.23 was not useful in the hybrid study however, as although it was easy to score in *H. laevigata*, a third allele of equal intensity to the first two was detected in some *H. rubra* samples, and in many of the hybrid progeny.

It should also be noted that the optimal conditions for PCR amplification would vary dramatically with different thermal cyclers. This was exemplified in the transfer of 6 *H. rubra* microsatellite loci that produced clean PCR products in *H. midae* in our study, but required extensive re-optimization when used in a genetic variation study in Cape Town, South Africa (Evans et al. in prep.). The most obvious reason for this discrepancy was the large variation in ramp times between the respective PCR machines. For this reason any attempt to transfer molecular marker technology between laboratories, and particularly between species will require additional PCR optimization at the new site. The substitution of specified reagents with those that are cheaper or more readily available may also affect amplification (Evans et al. in prep.).

One thing that is often overlooked when testing microsatellite primers is the design of the primer sites. The failure of a particular locus to amplify in another species may not mean that the microsatellite repeat is not present in that species, but simply that one or both of the primer sites have not been conserved. As the majority of microsatellite primers are published as part of a larger sequence on the Genbank (NCBI) database, the option of primer re-design is available. In this study, we have designed two pairs of primers for the *cmrHr*2.9 clone, with the *cmrHr*2.9 primers being internal to those of *cmrHr*2.15. What we have seen in this case is that the external primers (*cmrHr*2.15) were conserved in the South African species, *H. spadiceae*, while the internal primers (*cmrHr*2.9) were not (Table 2). It could be argued therefore that the examination of published sequences, and if necessary the re-design of primer sites, could be a more affordable solution to marker development than the creation of a new microsatellite library.

This study shows that microsatellite loci isolated from Australian blacklip abalone, *H. rubra*, can be amplified in some related *Haliotis* species, but that the likelihood of marker conservation is reduced with increasing phylogenetic distance. Rosetto et al. (1999) suggest that the selection of a single species from a large genera for microsatellite locus development will result in a suite of markers for most taxa in that genus. They detail only minimal PCR optimization for the transfer of markers between species of the *Melaleuca* genus. Scribner et al. (1996) provide examples of high levels of marker conservation in species ranging from whales to rodents to support their results in salmon and trout from Alaska, North America and the United Kingdom. What we have seen here, and in the previous study of abalone microsatellites (Huang & Hanna 1998) however, is a much lower rate of marker conservation between *Haliotis* species. This finding together with the very high levels of polymorphism encountered in most abalone species (*H. midae*, Evans et al. in prep. *H. asinina*, Selvamani et al. 2000: *H. rubra*, Evans et al. 2000), may point towards a more rapid mutation rate of microsatellite repeats in abalone than that seen in other organisms.

Research on the cross-amplification of microsatellite loci within taxa should ensure that the markers are useful within that species, and do not simply produce an amplification product. Our results have clearly shown that the presence of a similar sized PCR product on agarose gels is not sufficient to report locus conservation in another species. Future studies should therefore endeavor to test those products further by radioactive or fluorescent labeling methods similar to those that would be used in larger studies. This would ensure that only those markers that are likely to provide reliable genetic information would be considered by those commencing projects on these species.

ACKNOWLEDGMENTS

We thank Boze Hancock of Fisheries Western Australia for samples of *H. roei and H. Conicopora*, Liz O' Brien of the University of Queensland for samples of *H. asinina*, Dr. Neville Sweijd of the University of Cape Town, South Africa for samples of *H. midae* and *H. spadicea*, Phil Critchlow for samples of *H. scalaris*, Dr. Miguel Angel Del Rio of CICESE in Ensenada, Mexico for samples of *H. fulgens* and *H. corrugata*, and Dr. Rodney Roberts of the Cawthron Institute, New Zealand for samples of *H. iris*, *H. virginea* and *H. australis*. We would also like to thank Dr. Bob Ward and Dr. John Benzie for helpful comments on the manuscript.

INDUCTION OF TRIPLOIDY IN PACIFIC RED ABALONE (*HALIOTIS RUFESCENS*)

ROSALÍO MALDONADO,[1] ANA M. IBARRA,[1]* JOSÉ L. RAMÍREZ,[1] SUSANA AVILA,[1] J. ENRIQUE VÁZQUEZ,[2] AND LETICIA M. BADILLO[2]

ABSTRACT Induction of triploidy was evaluated in red abalone, *Haliotis rufescens*, using cytochalasin-B (CB). Three experiments were done at different times of the year and with different CB concentrations, but triploids were produced only in May and November. The largest percentages of triploids were obtained in the November induction (85%, 100%, 100%, for 0.5, 0.75, 1.0 mg/L CB, respectively), and poorer triploidy success was obtained in the May induction (3%, 11%, 26%, for 0.3, 0.5, 0.7 mg/L CB). When the induction was done in November CB concentration did not play a significant role in success of triploidy, although it did play a role on relative survival to trochophore, with the two highest concentrations resulting in lower survivals. For the May and September inductions, treatment with CB had a significant effect on survival, but this was independent of CB concentration. The results on triploidy success at each time of induction paralleled those for larval viability at each of those times of the year when evaluated in untreated control larvae, with the largest survival to trochophore (55%) and the lowest coefficient of variation (CV = 12%) for survival of untreated larvae produced in November. Untreated larvae produced in May had an intermediate survival (37%) and CV (57%), whereas that produced in September had the lowest survival to trochophore (1%) and the largest CV (143%).

KEY WORDS: red-abalone, *Haliotis rufescens*, triploid, egg quality, larval viability

INTRODUCTION

Pacific red abalone (*Haliotis rufescens*) is found from southern Oregon–northern California in the USA to the north of the Baja California Peninsula in Mexico (Cox 1962, Lindberg 1992). Aquaculture production of this species began during the last decade in Mexico, where the whole life cycle is managed under controlled conditions. The growth rate in this abalone is slow, reaching 120 mm to 160 mm in three to four years (Tegner & Butler 1985), and ways to improve production need to be defined. Triploidy, among other methods, has been proposed to improve production of abalone (Fujino 1992, Elliott 2000).

Triploidy has been induced in a wide variety of marine mollusks (Beaumont & Fairbrother 1991), with the pioneer work having been on oysters (Stanley et al. 1981). For most species, induction of triploidy in mollusks is done by inhibiting the extrusion of the second polar body during the conclusion of meiosis in fertilized eggs. Several induction methods have been tested; chemical treatment with cytochalasin-B (CB) or 6-dimethylaminopurine (6-DMAP), and physical treatment with hydrostatic pressure or thermal shock (cold or heat). In abalone species, Arai et al. (1986) and Kudo et al. (1991) were the first to report successful production of triploid abalone (*Haliotis discus hannai* and *Haliotis diversicolor diversicolor*) using thermal shock. Curatolo and Wilkins (1995) produced triploids of *Haliotis discus hannai* using hydrostatic pressure. Recently, Zhang et al. (1998) produced triploids of that same species using 6-DMAP, Yang et al. (1998a), Yang et al. (1998b) produced triploids of *Haliotis diversicolor* using thermal shock and cytochalasin-B, and Stepto and Cook (1998) produced triploids of *Haliotis midae* using cytochalasin-B. Powers et al. (1996) mentioned their success in producing and growing triploids of Pacific red abalone, *Haliotis rufescens*, although no details are given in the abstract.

In this study we report on the effects of induction to triploidy using different CB concentrations in east Pacific red abalone, *Haliotis rufescens*, during three times of the year.

MATERIALS AND METHODS

Three experimental inductions to triploidy were done at different times during the year 2000 in a private hatchery; late May, early September, and late November.

Spawning

Spawning and gamete collection procedures were the same for all experimental inductions. Mature spawners (10–15 cm shell length) of red abalone, *Haliotis rufescens*, were selected from the broodstock kept in the commercial farm 'Abulones Cultivados' at Erendira, Baja California, Mexico, and used to obtain eggs for the treatments. Spawning was induced following methods developed by Morse et al. (1977), by adding hydrogen peroxide dissolved (final concentration 0.02%) in seawater for a period of approximately two hours, or until spawning began.

Gamete Collection

Four sets or blocks were used for each of the three experimental induction times. Because the number of eggs shed by red abalone is not large enough to be able to divide the eggs from one female into different CB treatment concentrations, each set was composed of a mixture of eggs from 3–5 females. The sets were made sequentially, that is, eggs of the first three to five females that spawned were mixed to make the first set, and the other sets were made sequentially, each of them with 3–5 spawners. Eggs were fertilized by adding about 30 sperm per egg.

Triploid Induction

For each of the three experimental induction times, each set was divided into the same four treatment groups (one untreated control, and three CB treatment concentrations). For the May induction, the CB concentrations tested were 0.3, 0.5, and 0.7 mg L^{-1}; for the September induction 0.6, 0.8, and 1.0 mg of CB L^{-1} were tested; and for the November inductions the CB concentrations tested were 0.5, 0.75, and 1 mg L^{-1}. During the May induction, cytochalasin-B was added at the time at which the eggs in the

control group showed the beginning of the extrusion of the second polar body (PB2) and ended when 50% of the control group eggs showed the second polar body. On average, the treatment lasted 20 minutes. Water temperature during the induction was 15°C. Egg density for each treatment was 2×10^5 L^{-1}. For the inductions in September and November, CB was added when 50% of the eggs in control group showed the first polar body (PB1), and ended when 50% had the second polar body. For the September induction, treatment lasted from 19 to 55 minutes, depending on when 50% of the eggs in each set showed extrusion of PB2. Water temperature during treatments was 20°C, and egg density for all treatments was 1.2×10^5 L^{-1}. During the November induction, treatment lasted between 32 to 48 minutes, depending on the set. Water temperature during the induction was 14.5° C, and egg density for the treatments was 2.3×10^5 L^{-1}. For all three experimental induction times, after treatment with the different concentrations of CB, eggs were rinsed in DMSO (1 mL L^{-1}) for 15 minutes to remove any remaining CB (Allen et al. 1989).

Absolute and relative survival from egg to trochophore larvae (about 20 hours post fertilization) and absolute and relative survival from egg to postlarvae (about 120 hours post fertilization) were estimated for each treatment group and control for all experimental inductions. Relative survivals were estimated within each set and induction time as the ratio between the survival of the treated group to the survival in its control group, and expressed in percentages.

Ploidy success was estimated by flow cytometry (Ploidy Analyzer II, PARTEC Germany) of postlarval stages (approximately 200 / treatment / block), with the exception of the experimental induction in September, for which trochophore larvae (for those sets with surviving larvae) were analyzed. The flow cytometry methodology was that originally developed by Allen (1983), with modifications for larvae in Allen & Bushek (1992). In short, larvae were concentrated in a 1-ml suspension, centrifuged, and the pellet was stained with 0.5 ml of a DAPI/detergent/DMSO solution (Allen & Bushek 1992), re-suspending by vortex. Trochophore and postlarvae were disaggregated as in Allen and Bushek (1992); trochophore larvae by repeated aspiration with a 1 ml syringe, and postlarvae were disaggregated by means of crushing the meat/shell with a glass rod. In both cases, the obtained cell suspensions were passed through a 30-μm screen, adding 1.5 ml of the DAPI/detergent/DMSO solution before flow cytometry assay.

Larval Culture

After treatment, the embryos were kept in 100-L tanks until hatching. No feeding, aereation, or water flow was provided during this period (20 h). After hatching, swimming trochophore larvae was transferred to 150-L tanks at a stocking density of 4 larvae / ml, providing continuous flow. Trochophore larvae were induced to settle after 6 days following Morse et al. (1979) methodology, modified by Searcy-Bernal and Anguiano-Beltran (1998) by adding GABA (gamma-aminobutyric acid) at a final concentration of 1.6 μM. After settling, postlarvae was grown in 200-L circular tanks (112 cm diameter, 28 cm height) by placing 30,000 postlarvae / tank, feeding by inoculating each tank with 3000 cells/cm^2 of the benthonic microalgae *Navicula incerta*.

Statistical Analyses

For each experimental induction, the effect of CB concentration on mean larval survival, and mean triploid success (n = 4), was analyzed using a randomized block design analysis of variance (Neter et al. 1985). Set (block) was considered a random effect. Percentage data were transformed to arcsine for analysis (Zar 1999). Significance was set as at $P < 0.05$ for all analyses. Tukey pairwise comparisons were used to test for differences between means (Neter et al. 1985).

To establish whether there were differences in larval viability between dates of spawning regardless of CB treatments, the effect of experimental induction time on absolute survival of the control, untreated groups, was analyzed with the same model above.

RESULTS

The results on survival to trochophore and to postlarvae, and on success in triploid production for each experimental induction time are in Table 1.

Triploidy

Triploid abalone were successfully produced only during the May and November inductions. During the September induction, no triploids were detected in any of the tested concentrations. For the May induction, the highest concentration (0.7 mg CB L^{-1}) gave the best success in triploid production (26%), whereas the lowest concentration (0.3 mg CB L^{-1}) resulted in the lowest success in triploids produced (3%) which was not significantly different ($P > 0.05$) from the control (0% triploids). The intermediate concentration (0.5 mg CB L^{-1}) resulted in 11% triploids, which was not significantly different from the results using the lowest or the highest concentrations (Table 1A). There were no triploids detected in the control groups of any of the sets. For the November induction, all tested concentrations resulted in high success in triploid induction (Table 1C), all being significantly different from the control group, but not from each other. Only one of the four sets in the 0.5 mg L^{-1} treatment had less (40%) than 100% triploids. Success in triploidy ranged from 85% for the lowest concentration (0.5 mg CB L^{-1}) to 100% for the intermediate (0.75 mg CB L^{-1}) and highest concentration (1 mg CB L^{-1}) tested.

Survival

Treated and Control Groups—Within Experimental Induction Times

For the May induction, there were no significant differences in absolute survival to trochophore or postlarvae between the treated groups and the control (Table 1A). However, there were significant differences in relative survival to trochophore ($P < 0.05$), with the control group having a survival larger than both the 0.3 and 0.5 mg CB L^{-1} treated groups, but not than the 0.7 mg L^{-1} treated group. There were no significant differences between treated and control group for relative survival to postlarvae.

For the September induction, absolute survival to trochophore larvae was not different between concentrations or the control, but relative survival was significantly larger ($P < 0.05$) for the control group than for any of the treated groups, which did not differ significantly from each other. There were no surviving postlarvae in any group (Table 1B).

For the November induction, there were no differences in absolute survival to trochophore larvae between control and CB treated groups, but there were differences ($P < 0.05$) in absolute survival to postlarvae, with the control group showing the largest survival, and the CB treated groups not being different from each

TABLE 1.

Absolute and relative mean survival to trochophore larvae and postlarvae treated with different concentrations of CB, and percent of triploidy success in Pacific red abalone, Haliotis rufescens, induced to triploidy in (A) May, (B) September, and (C) November. n = 4 for all induction times.

CB Treatment	Absolute		Relative		
	Survival to Trochophore (%)	Survival to Postlarvae (%)	Survival to Trochophore (%)	Survival to Postlarvae (%)	Percent Triploidy
(A)					
Control	37^{a}	10^{a}	100^{a}	100^{a}	0^{a}
0.3 mg L^{-1}	20^{a}	5^{a}	56^{b}	54^{a}	3^{a}
0.5 mg L^{-1}	21^{a}	5^{a}	58^{b}	50^{a}	11^{ab}
0.7 mg L^{-1}	23^{a}	2^{a}	63^{ab}	24^{a}	26^{b}
(B)					
Control	0.96^{a}	0	100^{a}	0	0^{a}
0.6 mg L^{-1}	0.44^{a}	0	20^{b}	0	0^{a}
0.8 mg L^{-1}	0.46^{a}	0	34^{b}	0	0^{a}
1.0 mg L^{-1}	0.30^{a}	0	10^{b}	0	0^{a}
(C)					
Control	55^{a}	46^{a}	100^{a}	100^{a}	0^{a}
0.5 mg L^{-1}	48^{a}	23^{b}	84^{ab}	47^{b}	85^{b}
0.75 mg L^{-1}	31^{a}	12^{b}	56^{b}	24^{b}	100^{b}
1.0 mg L^{-1}	32^{a}	13^{b}	60^{b}	27^{b}	100^{b}

Within columns and experimental induction time, different letters are used when means are significantly different (ANOVA, $P < 0.05$).

other. Relative survival to trochophore larvae and to postlarvae was also different from the control group. The lowest relative survival to trochophore was seen for the two highest tested CB concentrations (0.75 and 1 mg L^{-1}), whereas the lowest CB concentration did not show significant differences with the control or the other tested CB concentrations. All treated groups had significantly lower relative survival to postlarvae than the control group (Table 1C).

Control Groups—Between Experimental Induction Times

Survival of trochophore and postlarvae in the control groups was significantly different ($P < 0.05$) between experimental induction times (Table 2). The highest survival was seen for larvae produced in November (55% to trochophore larvae, 46% to postlarvae), followed by larvae produced in May (37% to trochophore larvae, 10% to postlarvae). For the September spawn, there was only 1% survival to trochophore larvae, and no surviving postlarvae. The coefficients of variation for mean survival was high for the September induction, followed by May, and with the lowest CV the survivals in November.

TABLE 2.

Absolute means survival (%) and coefficient of variation (CV) from egg to trochophore and from egg to postlarvae of the control untreated groups, for each of the experimental inductions.

Induction time	Survival Mean % (CV) Egg to Trochophore	Survival Mean % (CV) Egg to Postlarvae
May	36.7^{b} (57)	9.6^{a} (62)
September	1.0^{a} (143)	—
November	55.3^{c} (12)	46.0^{b} (28)

Different letters within columns indicate significant differences between induction times.

DISCUSSION

Our results show that triploidy can be induced in red abalone, *Haliotis rufescens*, using cytochalasin-B (CB) to inhibit release of the second polar body, and that factors other than CB concentration can have an effect on success of triploid induction as evidenced by the different results obtained between May and November in spite of having used two equal CB concentrations. The cause for the variable success rate in triploids produced between the three experimental induction times is not known, but three possible causes might have been influencing the results, either independently or combined: different temperatures during the spawning and inductions, differences in the CB concentrations and duration of the inductions, and differences in egg quality of abalones used in each of those months.

During the three induction times the temperature was different only for the September induction, when a unusually high temperature of 20°C was recorded and a low survival to trochophore with no triploids produced, and no surviving postlarvae were observed. The effect of increased water temperature on larval viability during the spawning for this species is not known, and no inferences can be drawn with regard to this factor alone. Furthermore, in May and November the results on triploidy success were different between both inductions, but water temperature was about the same for both inductions, 14.5°C and 15°C. Whereas it is known that at least in oysters meiotic rates are increased as temperature increases (Downing & Allen 1987, Eudeline et al., 2000b), in our study meiotic rates were actually slower during the September induction (40 min for 50% PB1) than for the November induction (27 min for 50% PB1) in spite of the higher water temperature occurring during the September induction. This points toward another factor rather than temperature on itself being the cause of no success in triploid production during September. The second possible cause, CB concentration and duration of induction, can not explain completely the difference between induction times in September and

November because similar concentrations were tested, and in both cases the biological criteria defined by Allen and Bushek (1992) were used for the inductions; starting when 50% of the eggs showed the first polar body (PB), and ending when 50% showed the second PB. When the May and November induction results are compared, they indicated that CB concentration was important for the percentage of triploids produced only during the May induction but not during the November induction. However, this might be explained by differences in the duration of the induction between May and November, because induction in May was not started until the appearance in the first eggs of the extrusion of the second polar body, whereas in November it was started before, when 50% of the eggs had the first polar body. Given the shorter treatment duration in May resulting from this (20 min) when compared with the other induction times (>30 min), increasing CB concentrations might have been important in inducing a larger percentage of triploids during the short induction time in May. Supan et al. (2000) found that whereas increasing CB concentration was important for improved success in triploidy induction for the American oyster, *Crassostrea virginica*, a longer treatment time might have resulted in greater triploidy success. They used a fixed treatment time (10 min), which as in our case for the May induction, did not follow completely the biological criteria recommended by Allen and Bushek (1992) for triploid induction.

The third possible cause for the differences in triploidy success between induction times could have been differences in reproductive condition of the abalones between May, September, and November. There are few studies on the reproductive cycle of red abalone native to the study area. From the two found it is known that the reproductive cycle of red abalone in northern Baja California is active from May to December, reaching maturity around September (Ortiz-Quintanilla et al. 1990), with the spawning peak occurring between October and December (Molina-Martínez 1983). If during the year of the experiment the reproductive cycle followed that described, mature individuals should have been available at all three induction times, and in fact, they were. However, an observation during the induction times was that, even if available, mature spawners were more difficult to find at the farm during the May induction, and still more difficult to find in September than in November, when the largest success was seen in triploid production. Then, whereas the variable abundance of mature spawners appears to indicate that the egg quality was variable between those induction times, biochemical determination of egg quality was not done. However, alternative or indirect measurements of egg quality that do not involve biochemical determinations of reserves have been previously used in association with evaluations of triploid success. For example, Aldridge et al. (1990) used survival in the control groups as a measurement of egg quality, finding an association between survival in the controls and success in triploid induction in bighead carp. They proposed that egg quality, measured as larval viability in the control groups, could provide a good indicator of success in triploid production. In the present study survival in the control groups indicated also an association with triploidy success, with the highest survivals to trochophore larvae having seen during November, when the largest success to triploidy was obtained, and the lowest triploidy success was observed when the lowest survival occurred in the control groups. Furthermore, the coefficients of variation (CV) for mean survival to trochophore larvae in the control groups for each induction time, with the lowest CV seen for the November data, and the highest CV for the September data, are also indicative of large variability in survival being associated to low success in triploid production and low variability in survival with high success. The importance of evaluating survival in the control groups rather than in the treated groups as a potential indicator of success in triploidy is demonstrated by the fact that Allen and Bushek (1992) did not find a correlation between survival of treated batches or families of oyster eggs and success in triploidy, nor did Ruiz-Verdugo et al. (2001) when working with scallop eggs. However, the last authors found that the correlation between number of eggs and number of D-larvae in untreated groups was highly significant, whereas in the CB treated groups that correlation was lost, indicating that survival in treated groups is affected by factors other than egg quality, as for example, toxicity of the CB treatment itself.

The importance of egg quality in triploid induction of mollusks have been stressed by Utting and Doyou (1992), who demonstrated that variability in egg quality among the treated eggs of the Manila clam, *Ruditapes philippinarum*, can affect success during triploid induction. This is presumably caused by a lack of synchrony in meiotic rates, which are known to be highly important in triploid and tetraploid induction (Allen & Bushek 1992, Eudeline et al. 2000a). In the present study, there was evidence of lower synchronization in meiotic rates between the sets used during September than those used during November. That evidence comes from the coefficient of variation (CV) of meiotic rate between sets, measured as time to reach 50% of PB1, which was twice during the September induction (CV = 33%) than in November (CV = 16%).

In conclusion, success of triploidy in Pacific red abalone can be obtained when using CB concentrations from 0.5 to 1 mg L^{-1}, and when the induction is started when 50% of the eggs show extrusion of the first polar body. Larger concentrations of CB will result in lower survival of treated eggs, possibly as an effect of toxicity of the chemical. Variation among induced batches at different times of the year can be expected, and this might be a consequence of differences in the egg quality of the spawners at each time, although this has to be further evaluated using biochemical data.

ACKNOWLEDGMENTS

We thank the board of trustees and specially Mr. Benito Altamira-Rodriguez from the commercial farm Abulones Cultivados for their support in doing this research. We also thank Dr. S. K. Allen and Aimee Howe from ABC at the Virginia Institute of Marine Sciences, for the May induction analyses by flow cytometry. This research was supported by CONACYT grant 28256-B to A.M. Ibarra. The senior author is a CONACYT and SEP (DECYTM) PhD fellow, and the results presented here are part of his thesis. Dr. Ellis Glazier edited the English language text.

THE EFFECTS OF ENVIRONMENTAL FACTORS ON THE BIOCHEMICAL COMPOSITION OF THE BIVALVE *TAGELUS DOMBEII* (LAMARCK, 1818) (TELLINACEA: SOLECURTIDAE) FROM THE INTERTIDAL FLAT OF COIHUÍN, PUERTO MONTT, CHILE

G. X. URRUTIA,* J. M. NAVARRO, E. CLASING, AND R. A. STEAD

Instituto de Biología Marina "Dr. Jürgen Winter", Universidad Austral de Chile, Casilla 567, Valdivia, Chile

ABSTRACT Samples of *Tagelus dombeii* (eight adults of each sex ranging between 5.5 cm and 7.0 cm) were collected monthly from the tidal flat of Coihuin, Puerto Montt, Chile, between June 1995 and July 1996. The soft tissue was divided into gonad, digestive gland and remaining somatic tissue, which were dried before determination of dry weight and biochemical composition (protein, lipid, carbohydrate and ash). Several environmental variables were measured at the same time (temperature, salinity, seston, clorophyll *a*, phytoplankton). Data were standardized to one individual of 6.0 cm shell length and presented as monthly means ± s.d. for each sex.

There was no seasonal pattern in the dry meat weight of *T. dombeii*. The spring diatom bloom of 1995 was not reflected in an increase in dry body weight. The increases in the weights of the somatic fraction and the digestive gland during the winter of 1996, together with increases in all the biochemical components, were attributable to an unusual diatom bloom and a reduced metabolic expenditure associated with lower temperatures. The cycle in the biochemical components is reflected in the energy content, which follows the trend in the weight of the corresponding tissue.

There is an increase in the gonad weight and in the gonad index in *T. dombeii* in spring and a further increase in summer. Gametogenesis occurs initially at the expense of reserves accumulated earlier in the soma (principally carbohydrate and protein) or in the digestive gland (mostly lipid), resulting in decreases in the storage tissues as the reserves are transferred to the gonad. Subsequently, energy for gametogenesis is obtained directly from ingested food as this source becomes adequate. Nevertheless, whether gametogenesis is associated with high body condition or with an abundant food source, there is no decrease in the weight of the animal.

The annual variation in the biochemical components of the tissues is closely coupled to the availability of food, to temperature cycles that regulate metabolism and to the processes of gamete synthesis and release. Temporal fluctuations in environmental factors, especially temperature and food supply, drive the cycles of storage and utilization of metabolic energy reserves, which in turn govern growth and gametogenesis in this species.

KEY WORDS: bivalves, *Tagelus dombeii*, environmental variables, biochemical composition

INTRODUCTION

The annual and interannual variation in the availability of nutrients, in both qualitative and quantitative terms, seems to determine intraspecific variation in growth, reproduction and energy storage in bivalves (Newell et al. 1982, MacDonald & Thompson 1985a, MacDonald & Thompson 1985b, MacDonald & Thompson 1986, Emmett et al. 1987). In general, the synthesis and storage of protein, carbohydrate and lipid in molluscs occurs during those months in which food availability is greatest (Pieters et al. 1980, Ruiz et al. 1992, Hawkins et al. 1985, Emmett et al. 1987), these reserves being utilized when food becomes scarcer (Ansell 1974) or when metabolic demands such as those of gametogenesis must be met (Gabbott & Bayne 1973, Bayne 1976, Soniat et al. 1984, Soniat & Ray 1985, Emmett et al. 1987).

Depending on the availability of food and the size of the individual, energy may be allocated to the synthesis of body tissue, i.e., growth, or to the production. Ansell and Trevallion (1967) found that in *Tellina tenuis* dry body weight can increase by 44% when food is abundant and the gonad is developing, and decreases sharply during spawning. When the decrease in the weight of one or more tissues coincides with gonad development, one may conclude that the reproductive process is at least partly dependent on accumulated energy reserves. The weights of the digestive gland and adductor muscle decrease as gonad weight increases in *Patinopecten yessoensis* (Fuji & Hashizume 1974) and *Placopecten magellanicus* (Robinson et al. 1981). Thus reproduction is a process which requires a considerable expenditure of energy, obtained from recently ingested food or from the catabolism of reserves in the body tissues (Gabbott 1976, Gabbott 1983). In some species, such as *Pecten maximus* (Comely 1974) and *Chlamys opercularis* (Taylor & Venn 1979), energy reserves are laid down in summer for utilization during gametogenesis in the autumn, whereas in others, e.g., *Chlamys septemradiata* (Ansell 1974) and *Placopecten magellanicus* (Thompson 1977), the maximum food supply coincides with gonad growth and development. There are also species which can adopt either strategy, depending on the population (Thompson 1984, Gabbott 1983), or which utilize both strategies, depending on the time of year. Consequently, the seasonal variation in the biochemical composition of bivalve tissues is the result of complex interactions between environmental factors and metabolic processes (Gabbott 1975, Gabbott 1976, Gabbott 1983, Beninger & Lucas 1984, Thompson & MacDonald 1990), which are reflected in fluctuations in the dry weight of the different body tissues (Ansell 1972, Barber & Blake 1981, Shafee 1981).

In cold temperate environments the food supply to bivalves and physical factors exhibit considerable spatial and temporal variation (Vahl 1980, Dellarosa et al. 1993, Navarro et al. 1993, Stead et al. 1997, Toro et al. 1999). Navarro and Jaramillo (1994) concluded that the principal contribution of phytoplankton to the nutrition of suspension-feeders in the south of Chile, occurs during spring and summer, values being minimal during the rest of the year. Consequently, *Venus antiqua* exhibits a markedly seasonal growth pattern with high rates of growth in spring and summer (Clasing et al. 1994). Since the patterns of growth and reproduction in bivalves reflect environmental conditions (Trevallion 1971, Ineze et al. 1980, Chaparro & Winter 1983), it is likely that temporal changes in temperature and food supply are important in the regulation of

*E-mail: gurruti2@mercurio.uach.cl

biochemical cycles and reproductive processes. According to Shafee (1981) and Thompson and MacDonald (1990), these environmental variables can affect the biochemical components of the gonads of males and females in different ways, owing to the differences in the biochemical composition of the gametes.

The objective of the present study was to characterize and quantify the temporal variation in the biochemical composition (lipid, carbohydrate, protein and inorganic material) and weights of various body tissues in the bivalve *Tagelus dombeii* (Lamarck 1818), and to establish their relationships with several environmental variables (temperature, salinity, seston, pigments, phytoplankton) over the intertidal flat of Coihuín, Puerto Montt, Chile.

MATERIALS AND METHODS

Samples of *T. dombeii* were collected monthly between June 1995 and July 1996 from the intertidal flat of Coihuín (41°29′S; 72°54′W), located approximately 8 km SE from the town of Puerto Montt (Fig. 1). At each sampling time, water temperature and salinity were recorded and water samples (3 replicates of 2 liters volume) collected for determination of chlorophyll *a*, phaeopigments, particulate organic matter and particulate inorganic matter (Strickland & Parsons 1972). Additional water samples were fixed in Lugol's iodine for quantification of the principal phytoplankton taxa (diatoms and microflagellates).

For determination of tissue dry weight and subsequent biochemical analyses, 8 individual clams of each sex (determined by microscopic inspection of gonad smears), ranging between 5.5 cm and 7.0 cm valve length, were opened and the soft tissues separated into digestive gland, gonad and the rest of the tissue (soma). Separated tissues were dried at 60°C for 48 hours, weighed, ground in a ball mill (Retschmühle type MM) and stored at −20°C for biochemical analysis. Gonad and digestive gland indices were calculated as the dry weight of each tissue as the percentage of the total dry weight of soft tissues.

Carbohydrate, lipid, protein and ash were determined on subsamples of dried, homogenized tissue. Carbohydrate was estimated by the phenol-sulphuric acid procedure (Dubois et al. 1956) and lipid gravimetrically according to Bligh and Dyer (1959). Total nitrogen was determined with a CHN analyser (Perkin Elmer 2400) standardized with acetanilide, and protein calculated as 5.8 × N (Gnaiger & Bitterlich 1984). Ash-free dry weight was determined by combustion of dry samples for 12h at 500°C. Biochemical data were expressed as absolute values per standardized individual clam.

To express the biochemical data in terms of energy, values for the different tissues were multiplied by the appropriate conversion factors (protein: 24 $KJ \cdot g^{-1}$, lipid: 39.5 $KJ \cdot g^{-1}$, carbohydrate: 17.5 $KJ \cdot g^{-1}$, Gnaiger 1983).

Data for the dry weight, biochemical composition and energy content of the tissues were presented for males and females separately as monthly means with standard deviations. Values were corrected for a "standard" clam of shell length 6 cm, as described by Bayne et al. (1987):

$$W_S = (L_S/L_L)^b \times W_E$$

Where: W_S is the dry weight of the standard clam, L_S the standard shell length (6 cm), L_L and W_L the recorded shell length and dry weight respectively of the experimental clam, and b the weight exponent of the relationship between length and weight.

Student's *t*-test was used to test for differences between mean values for males and females. The relationships between dry weight, biochemical composition, food availability and physical factors were examined by correlation analysis and principal components analysis (Statistica 4.2 for Windows).

RESULTS

Environmental Factors

A seasonal cycle in water temperature was observed, with minimum values in winter (9°C in July 1995, 10°C in July 1996), increasing gradually until summer (17°C in January 1996). Salinity remained stable, varying between 24.9‰ in December 1995 and 32.4‰ in May 1996 (Fig. 2a).

Total particulate matter (seston) was highest in autumn-winter, reaching 10 $mg \cdot l^{-1}$ in July 1995 and 12 $mg \cdot l^{-1}$ in July 1996. During spring and summer values remained around 5 $mg \cdot l^{-1}$. The organic fraction of the seston exhibited a similar cycle (Fig. 2b), with minimum values (0.63 $mg \cdot l^{-1}$) in September 1995 and maximum values (5.57 $mg \cdot l^{-1}$) in June of the same year.

The concentration of chlorophyll *a* was lowest in summer (0.36 $\mu g \cdot l^{-1}$) and highest in April and May of 1996 (7.57 $\mu g \cdot l^{-1}$ and 8.61 $\mu g \cdot l^{-1}$ respectively). There were two minor peaks in July and September 1995 (Fig. 2c). Phaeopigment concentrations were lower than 2 $\mu g \cdot l^{-1}$ throughout 1995. In April 1996 a value of 7.8 $\mu g \cdot l^{-1}$ was recorded, probably as result of high zooplankton activity. Diatoms showed two main peaks (Fig. 2d), the first in November 1995 (5129 $cells \cdot ml^{-1}$) and the second in April and May 1996 (6954 $cells \cdot ml^{-1}$ and 5626 $cells \cdot ml^{-1}$ respectively), whereas high densities of microflagellates were observed only in the summer 1995–1996 (1833 $cells \cdot ml^{-1}$).

Dry Tissue Weight

Somatic Tissue

No large variations in the dry weight of somatic tissue of T. *dombeii* were observed during the study, although values were

***: Significant differences between males and females at the $P \leq 0.05$ level**
#: Significant differences between males and indeterminates at the $P \leq 0.05$ level
&: Significant differences between females and indeterminates at the $P \leq 0.05$ level.

slightly higher during autumn and winter, especially during 1996 (Fig. 3a). With a few exceptions, males and females did not differ in somatic dry weight ($P \leq 0.05$). This observation was confirmed by the lack of a significant difference between sexes when the overall annual mean was compared.

In some clams it was not possible to determine the sex owing to the scarcity of gonad tissue. These were classified as "indeterminate", and constituted the entire sample in June 1995 and May 1996. When indeterminate individuals were present as well as males and females, their somatic weight was similar to that of the females but significantly different ($P \leq 0.05$) from that of the males (Fig. 3a).

Gonad

Gonad dry weight increased markedly during spring and summer (Fig. 3b). No significant differences were found between males, females and indeterminate individuals, except in July and November 1995 ($P \leq 0.05$). Changes in gonad weight suggests one spawning in spring and another in summer, as also demonstrated by the gonad index. No significant differences were observed between annual mean values for males and females, although indeterminate individuals exhibited much lower values ($P \leq 0.01$).

Digestive Gland

Values increased during 1996 to reach maximum values in July (Fig. 3c). Significant differences ($P \leq 0.05$) were observed between mean values for males and females only in July 1995 and April 1996. The annual means for digestive gland were similar in males, females and indeterminates (>0.05).

Total Weight

The variations in total dry weight were similar to those exhibited by somatic weight, because the latter represented the major component throughout the year (Fig. 3d). There were no significant differences ($P > 0.01$) in overall mean total dry weight between males, females and indeterminates.

Gonad and Digestive Gland Indices

Minimum values were observed for the gonad index at the beginning of the study (June 1995, Fig. 4a), i.e., all individuals were indeterminate. During the spring, gonad index increased to peak values of 22.3% in males (November) and 18.3% in females (October) before decreasing in December to 9.8% (males) and 12.8% (females). A second peak was observed in February of 18.9% for males and 26.5% in females, to decrease to minimum values of 2% in autumn (April). Only in November 1995 there was a significant difference ($P \leq 0.05$) in gonad index between sexes. In those months in which clams of indeterminate sex were observed (Fig. 4a), such individuals exhibited the lowest gonad indices, suggesting that at these times the gonad was regressing and/or that gametogenesis was about to begin.

The digestive gland index remained relatively constant throughout the year (Fig. 4b). Values varied between 7.5% and 10.6% in males and 7.5% and 10.8% in females. Comparisons of monthly means showed significant differences ($P \leq 0.05$) between males and females in 6 months (Fig. 4b), but there was no significant difference overall ($P > 0.05$) between males and females.

Proximate Biochemical Composition

Composition of Somatic Tissue

The protein content varied from 551 mg to 865 mg in males, from 521 mg to 871 mg in females, and from 623 to 868 mg in indeterminate individuals, with slightly higher values in winter of 1995 and autumn of 1996 (Fig. 5a). Significant differences were observed ($P \leq 0.05$) between males and females in September, November and December 1995 and in April 1996, and between

#: Significant differences between males and indeterminates at the $P \leq 0.05$ level.

males and intermediates in July 1995 and April 1996. There were no significant differences ($P > 0.05$) in annual means between males, females and indeterminate clams. Lipid content varied between 44 mg and 63 mg in males, 38 mg and 74 mg in females, and 39 and 71 mg in indeterminate clams (Fig. 5b). No significant differences ($P > 0.05$) were observed between males and females in the annual means, although values were significantly different ($P \leq 0.05$) in March and April 1996. Carbohydrate content was lowest in spring-summer and highest in autumn-winter (Fig. 5c), reaching a maximum in July 1996. Intermediate values were observed in indeterminate individuals. Significant differences were only observed ($P \leq 0.01$) between annual means for indeterminate clams and those for males or females. Ash content varied between 101 mg and 154 mg in males and 84 mg and 151 mg in females, with means of 115 ± 28 mg, n = 83 and 114 ± 23 mg, n = 81, respectively (NSD, $P > 0.05$). Significant differences were observed ($P \leq 0.05$) between males and females in September 1995 and between males and females and males and indeterminate clams in April 1996 (Fig. 5d). The annual mean ash weight in

indeterminate clams was significantly different from that for males ($P \leq 0.01$) and females ($P \leq 0.05$).

Composition of the Gonad

In some months (June and July 1995, April and May 1996) insufficient tissue was available to undertake the biochemical analyses (indicated by "?" symbol, Fig. 6).

Protein content showed two rises (Fig. 6a): the first in October 1995 with the highest value for males (186 mg) and the second in February 1996 with the highest value for the females (221 mg). The lowest protein content was observed in August 1995 for both sexes (48 mg in males and 51 mg in females). Values for both sexes from September to November 1995 and from January and March 1996 were significantly different ($P \leq 0.05$). The average annual protein level in males was significantly different ($P \leq 0.01$) from that obtained for females. Lipids were notoriously higher in October and in February (Fig. 6b), at the time when gonad weight showed the highest values (Fig. 3b). There were no significant differences ($P \leq 0.05$) between the monthly averages nor in annual averages obtained for this component. The carbohydrates showed a similar tendency with marked increases in October and a maximum value in the case of the females in February. Figure 6c shows the months in which the monthly averages for both sexes were significantly different ($P \leq 0.05$). No significant differences were observed when annual averages were compared ($P > 0.05$). Ash content (Fig. 6d) increased significantly in November 1995 and in February 1996. Significant difference between males and females was only observed in July 1996. No significant differences were observed when compared annual means ($P > 0.05$).

?: without information by tissue scarcity.

Composition of the Digestive Gland

Protein was highest in July 1996 with a minimum value found in July 1995 in males and in December in the females; in indeterminate individuals protein fluctuated between 30 mg in July 1995 and 57 mg in April 1996 (Fig. 7a). There were significant differences ($P \leq 0.05$) between males and females in August 1995 and

T°: Temperature; Chl a: chlorophyll *a*; TS: Total Seston; OS: Organic Seston; Phyt: Phytoplankton; STW: Somatic Tissue Weight; GTW: Gonad Tissue Weight; DGTW: Digestive Gland Tissue Weight; GI Gonadal Index; S Prot: Somatic Protein; S Lip: Somatic Lipids; S Cho: Somatic Carbohydrates; G Prot: Gonadic Protein; G Lip: Gonatic Lipids; G Cho: Gonadic Carbohydrates; DG Prot: Digestive Gland Protein; DG Lip: Digestive Gland Lipids; DG Cho: Digestive Gland Carbohydrates. Marked values are significant at $P < 0.05$

February and April 1996, and between males and indeterminate individuals as well as between females and indeterminate individuals in July 1995 and April 1996. No significant differences ($P > 0.05$) were observed in annual averages of this component between males and females, although there were significant differences between the former and the indeterminate clams. Lipids increased in winter, being very high in July 1996. Minimum values occurred in spring-summer. Indeterminate clams showed values between 6 mg and 15 mg. Significant differences ($P \leq 0.05$) between males and females were observed in September 1995 and April 1996, between males and indeterminate clams in April 1996, and between females and indeterminates in July 1995. No significant differences ($P > 0.05$) were observed when comparing annual averages between males and females, although difference was observed ($P \leq 0.01$) in comparing these with the average lipid in the indeterminate individuals. Carbohydrates (Fig. 7c) showed a maximum in females in April 1996, a value which was significantly different from those obtained for males and indeterminate clams. Both sexes showed a minimum value in January (ca. 7 mg), with indeterminate clams showing a lower concentration in winter 1995 and a maximum in autumn 1996. Significant differences ($P \leq 0.05$) existed between sexes in October 1995 and April and July 1996, between males and indeterminate individuals in July 1995, and between females and indeterminate individuals in July 1995 and April 1996. No significant differences were observed ($P > 0.05$) when comparing annual means of males and females. The only significant difference ($P \leq 0.05$) was observed when males and females were compared with indeterminate individuals. The lowest ash content occurred in December and the maximum in January. Indeterminate individuals showed values ranging from 7 to 13 mg. There were no significant differences ($P \geq 0.05$) between males and females, with significant difference ($P \leq 0.05$) only between males and indeterminate individuals in April 1996 (Fig. 7d) . There were no significant differences ($P > 0.05$) when comparing the annual averages for males and females, but there was a difference observed ($P \leq 0.05$) between the average of both males and females with that of the indeterminate clams.

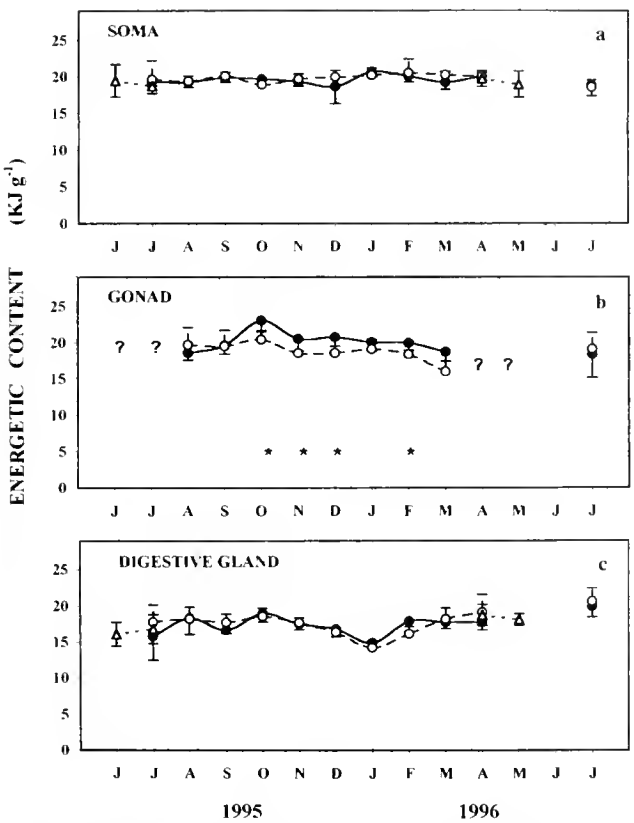

Figure 8. ***T. dombeii.*** **Temporal fluctuation in the energetic content of the different tissue. Data presented as, monthly means ± s.d. of males (●), females (○) and indeterminates (△).**

?: Without information by tissue scarcity.

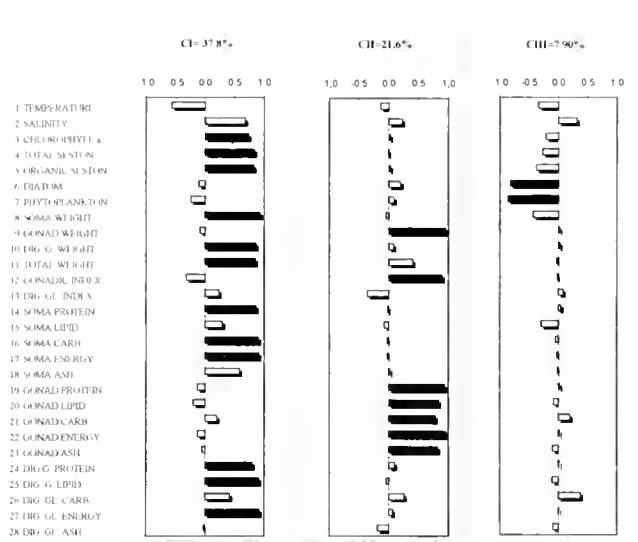

Figure 9. ***T. dombeii.*** **Principal Components analysis indicating the charge of each variable and the variance in each component. The black bars present charge ≥0.7, indicating significant association among variables.**

Energetic Content

No variation in the energetic content of the somatic tissue was observed (Fig. 8a), with no significant differences between males and females. When annual averages were compared, no significant differences ($P > 0.05$) were obtained between males, females and indeterminate clams. The energetic content of the gonad tissue increased in males, beginning in August 1995 (Fig. 8b). Significant differences ($P \leq 0.05$) were observed between males and females in October, November and December 1995 and February 1996. The annual average for males was significantly different ($P \leq 0.05$) than the average obtained for females. The energetic content of the digestive gland increased notably in July 1996 (Fig. 8c), with the minimum value for both sexes in January of this year. No significant differences ($P > 0.05$) were observed between males, females and indeterminate clams. Annual averages for energy content in the digestive gland did not show significant differences ($P > 0.05$) between males, females and indeterminate individuals.

Principal Components Analysis

The principal components analysis included 28 variables (Fig. 9), with 140 values estimated for 70 males and 70 females. Sex was not identified as an influencing factor and thus results from males and females were combined in the analysis. The variables with a charge ≥0.7 are associated with the variable component,

and as well, associated among themselves (Fig. 9). The three components explain 67.3% of the total variance. The first component associate positively chlorophyll *a*, total seston, organic seston, body weight, digestive gland weight, total weight, protein, carbohydrates and body energy content and protein, lipids, and energetic content of the digestive gland. In the second component are positively associated gonad weight, gonad index, protein, lipids, carbohydrates, energetic content and gonad ash. In the third component are positively associated diatoms and phytoplankton.

DISCUSSION

Environmental Variables

The annual cycles of temperature and salinity measured were similar to those previously described for the south of Chile (Navarro et al. 1993, Navarro & Jaramillo 1994, Stead et al. 1997, Toro et al. 1999). The concentrations of total and organic seston were lower than those reported by Navarro et al. (1993) for the tidal flat at Yaldad, (Chiloe). The total seston reached 12 $mg \cdot l^{-1}$ and the organic seston 5.6 $mg \cdot l^{-1}$, while at Yaldad, total seston reached 48 $mg \cdot l^{-1}$ and organic seston 18 $mg \cdot l^{-1}$. These differences were due to variations in primary productivity and terrigenous imports, as well as characteristics of sediments which facilitate resuspension. The highest concentrations of total and organic seston measured at Coihuin in winter 1995 were related to resuspension phenomena, in contrast with autumn-winter 1996 where they were related to the high primary production. Chlorophyll *a* rises in spring, as described for southern Chile (Navarro et al. 1993, Navarro & Jaramillo 1994, Stead et al. 1997, Toro et al. 1999) and for similar latitudes in the northern hemisphere (MacDonald & Thompson, 1985a; Navarro & Thompson Jr., 1995). A major rise was observed from April to July 1996, related with a diatom bloom. Phaeopigments showed a similar pattern to chlorophyll *a* but with lower values. In February and April 1996 high concentrations of phaeopigments were observed, probably attributable to excretion products due to an increase in grazing activities of zooplankton or, as a result of senescence of the phytoplankton (Hallegraeff 1981, Welschmeyer & Lorenzen 1985).

The phytoplankton consisted primarily of diatoms and microflagellates. The diatoms, primarily represented by *Skeletonema costatum*, showed major abundance in spring and fall, which was reflected by the increase in chlorophyll *a* as well as for total and organic seston. The greatest abundance of microflagellates occurred in December 1995 however, this was not reflected by chlorophyll *a* nor by the seston values, given the low biomass of this group.

Fluctuation in Weight and Energy Reserves

Numerous studies have demonstrated that the variation in weight in bivalves is related to reproductive cycles and environmental conditions (Thompson 1977, Sundet & Valh 1981, Jaramiilo & Navarro 1995). Temperature is commonly mentioned as a factor which influences growth and accumulation of metabolic reserves in bivalves (Bayne & Worral 1980, Vahl 1980, MacDonald & Thompson 1985a). However, Shafee (1981) concluded that the increase in weight of tissues was directly linked to the abundance of food available, Sastry 1966 and Sastry and Blake (1971), showed that temperature affected the initiation of gametogenesis in *Acquipecten irradians*, regulating the transfer of nutritive reserves from other tissues into the gonad. In *Mytilus edulis* (Thompson & Bayne 1974), *Donax trunculus* (Ansell et al. 1980) and *Modiolus modiolus* (Navarro 1990), the body weight demonstrated marked seasonal cycles with minimum values in winter and maximum in spring-summer in periods of high food availability. Conversely, *Tagelus dombeii* did not show a clear seasonal pattern, only presenting a rise in tissue weight in winter 1996, which may have been related to the unusually high concentration of diatoms occurring since autumn of that year. The situation was reflected by increase in weight of all body tissues, rise in carbohydrates and protein in somatic tissues, and in all biochemical components of the digestive gland. Interannual differences in tissue weights and cycles of metabolic reserves have been described for other species (Newell et al. 1982, Navarro 1990), and may be the result of yearly changes in environmental conditions.

The decrease in gonad weight and all their biochemical components from October to December, indicates the occurrence of a massive spawning during this period, as it was reported previously for this population by Clasing et al. (1998). The lack of increased body weight during these months, in spite of the abundance of phytoplankton, may be interpreted as a reduction in filtering activity during spawning periods as an adaptive mechanism for avoidance of ingestion of their own gametes (Newell & Thompson 1984, Thompson 1984). Also, during this period the natural rise in temperature may have resulted in higher metabolic demands.

Based on these results, the reproductive cycle of *T. dombeii* did not have a major influence on the body weight of this species. However, the initiation of gonadal development in winter 1995 coincided with a decline in the weight of the somatic tissue, suggesting that the initiation of gametogenesis occurred at the expense of reserves in this tissue. This is supported by a significant negative correlation between gonad weight and somatic carbohydrate ($r = -0.59$). Even when they were not significant at $P > 0.05$, (Table 1) a negative correlation was also observed between the gonad weight and the somatic protein ($r = -0.26$) and the lipid content of the digestive gland ($r = -0.20$). The digestive gland of *T. dombeii* did not show a decline during this season, although its lipid content decreased. Both conditions have been described for *Chlamys operculatis* (Taylor & Venn 1979) and *Placopecten maximus* (Faveris 1987) where the gonadal development in winter caused a decline in carbohydrates and protein in the adductor muscle, and a decline in lipids in the digestive gland. Under conditions of food scarcity, it has been suggested that glycogen acts as the primary energy reservoir for the formation of gametes in bivalves. Also a reduction of this reserve in storage organs is commonly correlated with an increase in gonadal lipids (Barber & Blake 1981, Benninger & Lucas 1984).

The considerable increase for gonad weight, gonadal index, and all biochemical components of the gonad of *T. dombeii* in February 1996 was related to the absorption of nutrients from the food, with significant positive correlations with chlorophyll *a*, organic seston and phytoplankton (Table 1). This suggests that this clam is able to take advantage of particulate food matter resuspended by tidal movement, waves, and winds. Minor water movement is sufficient to resuspend food particles at the bottom/water interface where this species remains buried with its siphons open at the sediment surface. Clasing et al. (1998) suggest there may be high concentrations of food material for this species at the sediment surface, given that the amount of chlorophyll *a* on the surface of the Coihuin tidal flat is somewhat greater than that encountered in the water column.

The majority of studies on the biochemical composition of bivalves describe temporal variations in components of different

tissues, comparing different populations, stages of maturation, stages in the life cycle, size classes, etc. Some studies have compared biochemical composition between males and females (Shafee 1981, Davis & Wilson 1983, Ruiz et al. 1992, Thompson & MacDonald 1990). Shafee 1981 suggested that during gonad development of *Chlamys varia*, protein was more abundant in males than in females, while these contained more lipids given the different composition of the gametes. Davis and Wilson (1983) described different levels in lipids between males and females of *Nucula turgida* only during the spawning season, with females having higher levels than males. Thompson and MacDonald (1990) found that lipids of *Placopecten magellanicus* varied from 3% to 19% in females in the spring, with no variation in males. Conversely, *T. dombeii* showed no significant differences in average monthly values for lipids between gonads of males and females. Content of protein in the male gonad was significantly higher than in the females. Carbohydrates in male and female gonads were significantly different only during the second period of gonad development which may be related to differential transformation of carbohydrates to lipids, as has been reported for other species (Gabbott 1975, Zandee et al. 1980).

Results obtained in April 1996 on comparative tissue weights between males and females suggested that the females were able to take better advantage of food availability than males, as during a large diatom bloom the females preferentially increased in weight of the fraction somatic and the digestive gland (thus total body weight). Also in this month, protein, lipid, and ash increased in female body tissues, as well as in organic components of the digestive gland. Thus, differences observed between sexes may occur during particular situations, rather than as part of annual cycles of storage and use of tissue reserves. During May, our sampling included only indeterminate individuals that had spawned were in regression, or which were initiating gametogenesis. A parallel histological study on *T. dombeii* (Clasing et al. 1998) concluded that during this month 57% of males and 80% of females were found in early active of gametogenesis, while 43% of the remaining males and 20% of the females were in the recovery stage. Also, 10% of the population was in an "indeterminate" stage, post regression and prior to gametogenesis, where sex determination could not be made. In May, indeterminate individuals underwent increases in somatic tissue weight and lesser increases in gonad weight in the presence of high diatom concentrations. The weight of the digestive gland of indeterminate individuals increased compared with males from the previous month. At that time, an increase in all biochemical components was observed in the somatic tissue, except for the lipids (gonad could not be sampled due to scarcity of this tissue). Also, a decrease was observed in proteins and carbohydrates of the digestive gland, with an increase in ash content. These observations suggested that nutrients coming from the phytoplankton were rapidly transferred from the digestive gland to other tissues as maintenance energy, for growth and to sustain incipient gametogenesis. This agrees with Gabbott (1976), who suggested that when sufficient food was available during gametogenesis, there was rapid transfer of assimilated food from the digestive gland to the other tissues. According to Thompson (1972), this transfer may occur within about seven days.

The energy available for the production of gametes may be affected by metabolic stress, such as produced by parasitism (Sanders 1966, Sanders & Lester 1981). Periodical sampling of the *T. dombeii* population at Coihuin revealed a high incidence of parasitism by a digenetic trematode (Familia Philophthalmidae), infestation could reach at times 100% of the adult population, but it rarely caused castration of individuals (<2.5%) (Yañez 1998).

In the principal component analysis, the first component associated positively the chlorophyll *a* and seston with the weight of somatic tissue and that of digestive gland, as well as with energetic content of these tissues. In the second component, the variables related to the gonad. This situation was expected, considering that the somatic tissue and digestive gland are organs of storage, constituting the main body of the organism, and that the gonad only develops in certain seasons of the year and depends as much on body reserves as on food availability.

The cycle of biochemical components in body tissues and digestive gland of *T. dombeii* at Coihuin is related to the production and liberation of gametes. Initiation of gametogenesis in winter takes place at the expense of stored tissue reserves, until food availability at the beginning of spring is able to continue to support this process. This situation has been described for *Chlamys operc*ularis (Taylor & Venn 1979), *Placopecten magellanicus* (Comely 1974, Faveris 1987) and *Mytilus edulis* (Zandee et al. 1980). Given that the increase in weight of the gonad coincides with a high condition of the organism, or elevated of food availability, gametogenesis does not provoke a decrease in body weight of individuals. Environmental variables such as temperature, which regulates metabolism, and food availability which provides necessary energy, play fundamental roles during the process of storage, distribution and utilization of energy reserves of *T. dombeii*. Temporal and spatial differences in these variables are reflected in the growth and gametogenesis of this species.

ENERGETICS VARIATION OF THE STRIPED CLAM *EURHOMALEA EXALBIDA* (CHEMNITZ, 1795) IN USHUAIA BAY, BEAGLE CHANNEL (54°50′S)

BETINA J. LOMOVASKY,[1]* ELBA MORRICONI,[1] AND JORGE CALVO[1,2]

[1]*Centro Austral de Investigaciones Científicas (CADIC-CONICET),C.C.92 – Ushuaia (V9410BFD),Tierra del Fuego, Argentina;* [2]*UNPSJB, Sede Ushuaia*

ABSTRACT The processes of energy transfer in the clam *Eurhomalea exalbida* Chemnitz, 1795 can be analyzed by measuring the seasonal variations in energy content with respect to the reproductive characteristics of the population. The energy content of three organ groups of *E. exalbida* (gonad, digestive gland and gastrointestinal tract-foot (FV); adductor muscles (M); and gills-mantle-siphons (GMS), was measured using calorimetry in monthly samples of the Ushuaia Bay population for a year. The relative condition index was also measured monthly for the three organ groups. No relationship was found between the energy content per gram (kJ/g ash free dry weight) of the organ groups FV, M and GMS and the size of the adult organisms. The mean values for the twelve month experimental period for FV were very similar for males and females with 20.55 ± 1.10 kJ/g for males and 20.26 ± 0.91 kJ/g for females; for M they were 20.68 ± 0.65 kJ/g for males and 20.76 ± 0.76 kJ/g for females; and for GMS they were less than for the other two organ groups, with values of 20.02 ± 1.09 kJ/g for males and 20.02 ± 0.84 kJ/g for females. An analysis of the energy content data and the relative condition index (RCI) measured at monthly intervals throughout the year revealed significantly lower values for FV in November ($p < 0.05$), which is believed to be linked to the greater gametic emission in this month. In contrast, no significant differences over time were found in the energy content or relative condition index of either M or GMS. The relative stability of the energy content and RCI of M and GMS over time suggests that there were no changes in the proportion of their biochemical components and no changes in the mass of the organs, hence *Eurhomalea exalbida* does not have an energy reservoir and the energy used in reproduction may be extracted directly from the food consumed.

KEY WORDS: energetics, clams, calorimetry, *Eurhomalea exalbida*, bivalve, Beagle Channel

INTRODUCTION

An understanding of the energy balance of an organism is based on knowledge of the temporal variation in energy acquisition and its use in maintenance, growth and reproduction. Physiological processes in temperate and cold water bivalves are also strongly influenced by seasonal variations in temperature and the availability of food (Mann 1979, Newell & Branch 1980, Smaal et al. 1997), thus patterns of growth and reproduction vary seasonally for each species. Variation in these activities has been shown to be correlated with changes in the energy content of different organs (Jobling 1994, Lucas 1996), thereby reflecting the spatial and temporal energy distribution within the organism. This distribution closely reflects the seasonality of the cost of reproduction and the capacity to accumulate reserves (Zandee et al. 1980, Robinson et al. 1981, Navarro & Torrijos 1995, Martínez & Mettifogo 1998).

Many investigations have examined variations in the energy content of different bivalve organs in relation to reproductive cycles, growth and basal metabolism. In such studies, the biochemical analysis of tissues (Beukema & De Bruin 1977, Beukema & De Bruin 1979, Zandee et al. 1980, Robinson et al. 1981, Sundet & Vahl 1981, Hérald & Deslous-Paoli 1983, Martínez & Mettifogo 1998), methods involving measures of the metabolic rates of live organisms (Newell & Branch 1980, MacDonald & Thompson 1986, MacDonald & Bourne 1987, Widdows & Johnson 1988, Sukhotin 1992, Smaal et al. 1997) and direct measures of caloric content by complete combustion (Beukema & De Bruin 1979, Griffiths & King 1979, Hérald & Deslous-Paoli 1983) have been used. Bomb calorimetry is an accurate method for measuring the energy content in aquatic organisms (Beukema & De Bruin 1979, Hartman & Brandt 1995, Lucas 1996).

Eurhomalea exalbida (Chemnitz 1795) is a species with a wide geographic distribution, from the Beagle Channel (54°50′S) to the island of Chiloe (42°S) in the Pacific littoral zone (Soot-Ryen 1959, Dell 1964, Osorio et al. 1979) and to the province of Buenos Aires (36° S) in the Atlantic littoral zone (Carcelles 1944, Carcelles 1950). *E. exalbida* is commercially exploited in various regions, although management practices are not generally used as very little is known of the clam's biology and the environmental factors that influence its populations. The Beagle Channel population represents the extreme south of the species' distribution, withstanding large temperature variations (4°C–11°C), with marked seasonal variation in the biomass of phytoplankton (Hernando, pers. comm.). These conditions may cause temporal fluctuations in the energy content of this population.

The purpose of this study was to analyze the temporal variation in the energy content of different organs in *E. exalbida* in relation to its reproductive cycle.

METHODS

Samples were collected in Ushuaia Bay (54°50′S, Beagle Channel), in a subtidal flat with a depth between two and four meters at low tide. Monthly sampling was conducted by SCUBA diving from October 1998 to September 1999. Monthly mean surface temperature was recorded. Clams with shell lengths greater than 38 mm ($n = 246$) were caught and kept in aquaria for 24 hours. Shell length (anterior-posterior axis, SL), measured with electronic calipers to the nearest 0.01 mm, and total weight (TW, ±0.1g) were recorded for each individual.

Calorimetric samples were identified and stored at −20°C until processing. After removing the valves, the sex of each individual was determined using gonad smears and the soft parts were separated into 3 groups: foot-visceral mass (gonad, digestive gland and gastrointestinal tract) (FV), adductor muscles (M), and gills-mantle-siphons (GMS). These divisions were made based on the presence or absence of gonads in the tissues and on their potential capacity to fulfill a storage function: FV includes all the tissues where gonads are present; M plays an important role as a reserve

*Corresponding author. E-mail: betinal@hotmail.com

organ in some bivalve species; and GMS is made up of all the other tissues where gonads are not present. Although it was not possible to separate the gonad tissue from the visceral mass, the calorimetric analysis of the soft parts separated as described above was considered to give more information about the energy balance of the species than an analysis of the organism as a whole. The soft parts were dried at 80 C to constant weight.

The relationships between shell length and FV dry mass, M dry mass and GMS free dry mass are represented by 1) log (Mass) = a + b × (log (SL)). Monthly condition values were analyzed using 2) condition index (CI) = Mass/Shell length ^{b}, where b is the slope in (1), and were normalized using 3) (RCI) = (CI − mean CI)/(S.D. of CI) to give a relative condition index.

The caloric contents of approximately 20 individuals per month were obtained by burning pellets (25–200 mg) in a Parr model 1425 micro-bomb calorimeter, as described by Beukema and De Bruin (1979) and Lucas (1996). The values obtained were corrected for ash and acid contents and were expressed as kJ/g ash free dry weight (AFDW).

Statistical Analysis

A regression analysis was performed with the energy content of the different organ groups as the dependent variable and the size of the organisms (SL) as the independent variable.

The monthly differences in relative condition index and energy content in each of the groups of organs (FV, M and GMS) were analyzed using an analysis of variance (ANOVA). The assumptions of normality and homogeneity of variances were tested and the appropriate transformations were applied when necessary. When this was not possible, a non-parametric test was used (Kruskal-Wallis). Unplanned comparisons were made (STATISTICA software) when significant differences were found.

After verifying Tukey's assumption of non-additivity (BIOM-STAT software), an analysis of variance (ANOVA) for randomized block design (RBD) was used to determine if there were differences in energy content (kJ/g AFDW) among FV, M and GMS for each month and both sexes. When significant differences were found among organ groups, unplanned comparisons were made (Zar 1984, Sokal & Rohlf 1995).

RESULTS

An analysis of the relative condition index for FV over time showed the highest values in January and February in both sexes, whereas the lowest values occurred in November and April for females and November and August for males. These results were highly significant (one-way ANOVA; $F_{\alpha=0.05,\ 11,\ 109} = 2.84$ $p < 0.002$ females and $F_{\alpha=0.05,\ 11,\ 113} = 3.96$ $p < 0.001$ males; modified Tukey test, $p < 0.05$). Theses results coincide with the gametogenic cycle observed for this species (Morriconi et al. unpubl.). No significant changes in the relative condition index over the experimental period were found for either M or GMS in either sex (one-way ANOVA, $p > 0.05$, Fig. 1). The minimum mean seawater temperature (4.5 C) was recorded in August and the maximum (8.7 C) was recorded in January (Fig. 2).

Linear regressions were used to determine the possible relation between the energy content (kJ/g AFDW) of the three organ groups (FV, M and GMS) and the size of the clams (SL). The results were not significant ($p > 0.05$) for FV ($R^2 = 0.001$) and GMS ($R^2 = 0.0002$) and were significant for M although only 6% of the total variation is explained by the regression ($R^2 = 0.06$).

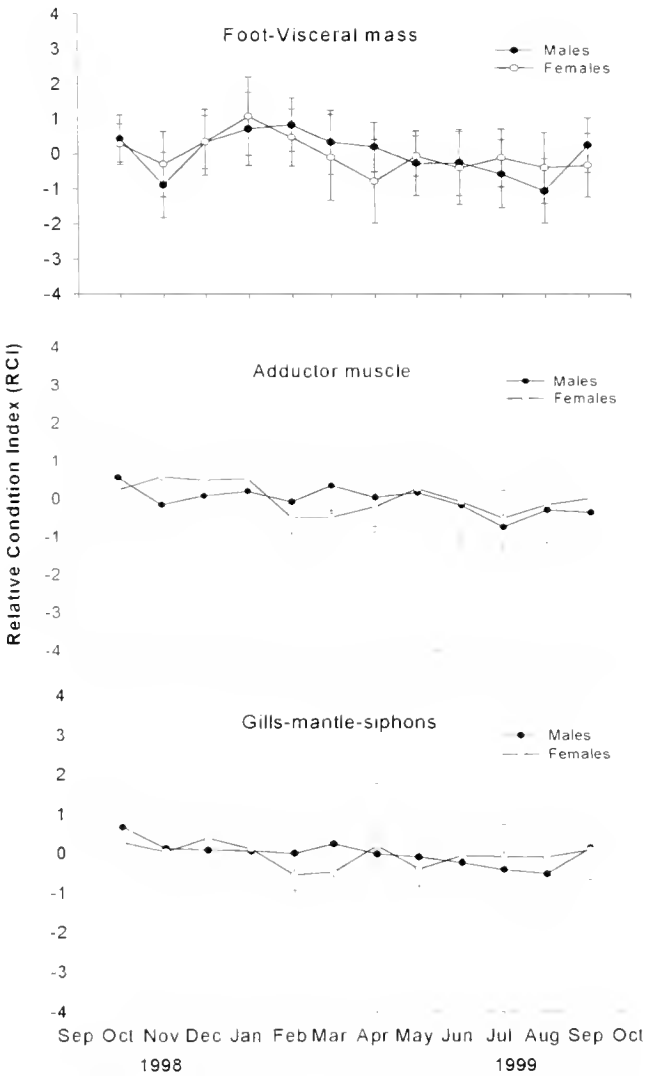

Figure 1. Mean and standard error of the relative condition index for foot-visceral mass, adductor muscles and gills-mantle-siphons over the experimental period for females and males of *E. exalbida*.

As caloric content per gram was found not to be related to the size of the organisms analyzed in this study, an analysis of variance (ANOVA) was used to analyze the variations in energy content.

Foot-Visceral Mass (gonad, digestive gland and gastrointestinal tract)

The mean energy content of FV over the experimental period for females (n = 121) and males (n = 125) were very similar (Figs. 3a and 3b respectively), at 20.26 ± 0.91 kJ/g AFDW for females and 20.55 ± 1.10 kJ/g AFDW for males.

The differences among the months were highly significant (one-way ANOVA) in both males ($F_{\alpha=0.05,\ 11,\ 113} = 4.32$, $p < 0.001$) and females ($F_{\alpha=0.05,\ 11,\ 109} = 3.39$, $p < 0.001$). It was shown in the unplanned comparisons (modified Tukey test) that the energy content for females was significantly lower in November and March ($p < 0.05$), and in October and February (the months prior to the decrease) the maximum energy content was observed although statistical significance was not obtained. The only significant variation in energy content among males occurred in November and the energy content was significantly less ($p <$

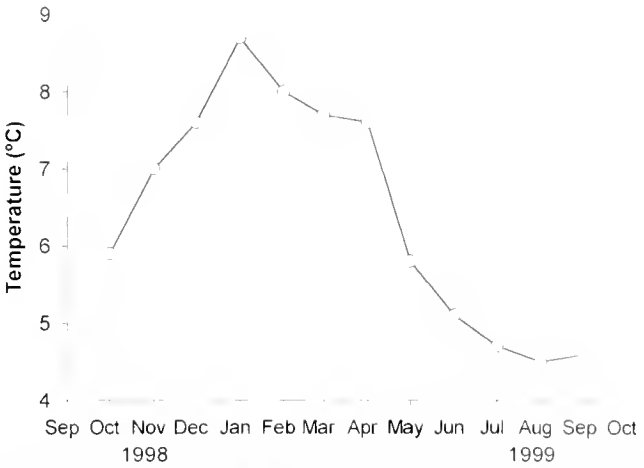

Figure 2. Monthly means of sea water temperature in Ushuaia Bay, Beagle Channel.

0.05) than in the rest of the year. Another decrease occurred in March, and in the months before these declines the greatest values were obtained.

Adductor Muscle

The mean energy content of M over the experimental period (Fig. 4a, Fig. 4b) was 20.76 ± 0.76 kJ/g AFDW (n = 121) for females and 20.68 ± 0.65 kJ/g AFDW (n = 125) for males. No significant differences were found in the energy content of M attributable to either sex ($F_{\alpha=0.05,\ 1,\ 222} = 0.08$, $p > 0.05$), time ($F_{\alpha=0.05,\ 11,\ 222} = 0.77$, $p > 0.05$), or their interaction ($F_{\alpha=0.05,\ 11,\ 222} = 0.47$, $p > 0.05$) (two-way ANOVA).

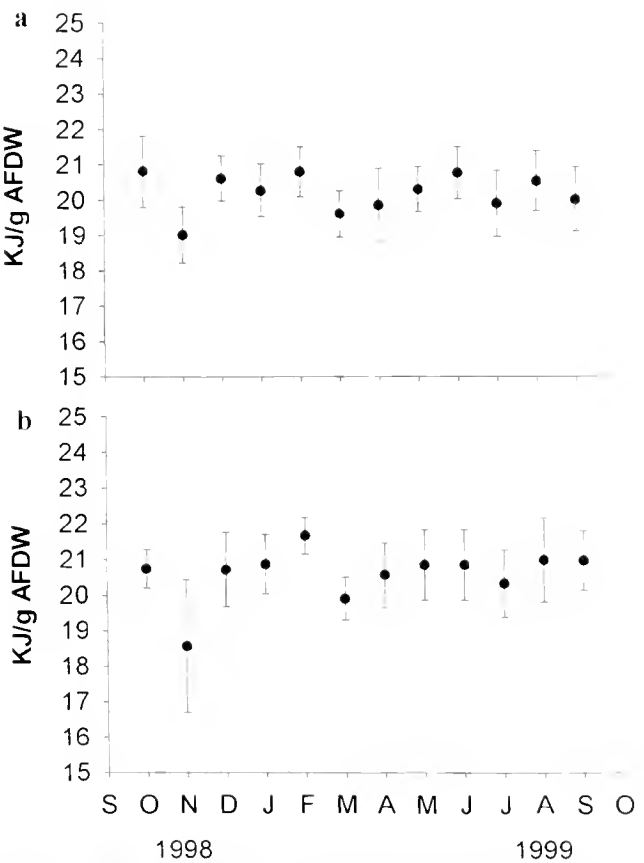

Figure 3. Mean and standard error of the energy content for foot-visceral mass (kJ/g AFDW) over the experimental period for (a) females and (b) males of *E. exalbida*.

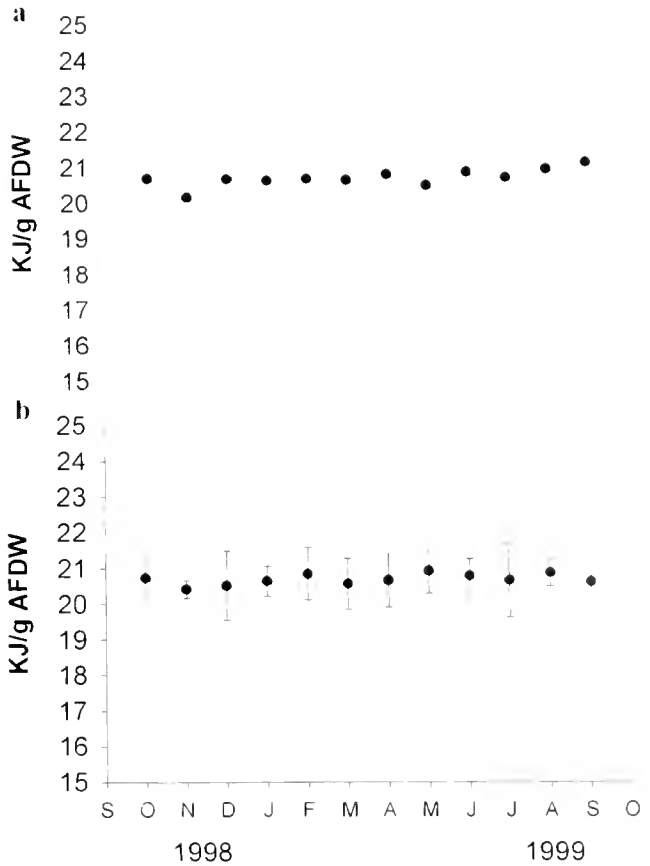

Figure 4. Mean and standard error of the energy content for adductor muscles (kJ/g AFDW) over the experimental period for (a) females and (b) males of *E. exalbida*.

Gills, Mantle, Siphons

The mean energy content of GMS over the experimental period (Fig. 5) was 20.02 ± 0.84 kJ/g AFDW for females (n = 121) and 20.02 ± 1.09 kJ/g AFDW for males (n = 125). No significant difference was found in the GMS energy content for males over time (Kruskal-Wallis; H = 16.29, $p = 0.1307$). In contrast, for females there were significant differences in energy content (one-way ANOVA, $F_{\alpha=0.05,\ 11,\ 109} = 2.58$, $p < 0.01$), with the lowest values in December and April and the maximum value in June (modified Tukey test: $p \cong 0.05$).

Variation Among Organ Groups

The monthly measures of energy content in the different groups of organs in both sexes (Fig. 3, Fig. 4, Fig. 5) show a marked stability in energy content for M, while for FV and GMS the variation was greater. A one-way ANOVA for RBD revealed significant differences ($p < 0.05$) among the energy content of FV, M and GMS (Table 1). This result suggests a difference in the biochemical composition of the organ groups.

In order to determine the organs responsible for these differ-

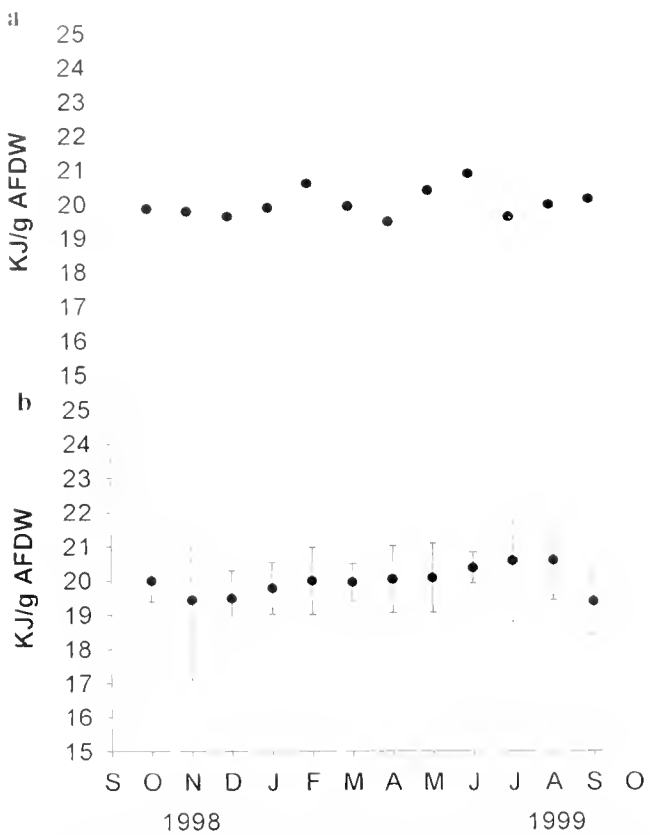

Figure 5. Mean and standard error of the energy content for gills-mantle-siphons (kJ/g AFDW) over the experimental period for (a) females and (b) males of *E. exalbida*.

ences, unplanned comparisons were made using the Tukey test. The energy content for both sexes was lower for GMS than for FV and M for most of the year, and in many instances these differences achieved statistical significance (Table 2; $p < 0.05$). The greatest difference in energy content occurred in November and March and is attributable to the large decrease in FV energy content, with lower values than for M and GMS.

DISCUSSION

Calorimetric analysis of the energy content of different organs allows the processes of energy transfer at the individual and population levels to be understood for a given species, yet such studies in clams are scarce. In *E. exalbida*, as in clams in general, it was not possible to separate each organ, and the organ groupings used here may mask some differences among the individual organs. Notwithstanding, the results obtained have yielded valuable information about annual energy variations in specific locations within the clam.

In this study of *E. exalbida* no significant regression was found between energy content per gram and the size of the individuals being studied for FV and GMS, and for M the regression was significant although only 6% of the variation in energy content was explained by size. As the amount of energy used for growth and reproduction is different for juveniles and adults (Griffiths & King 1979, Héral & Deslous-Paoli 1983, Smaal et al. 1997), only adult individuals larger than the size at first sexual maturity (SL = 40 mm) (Morriconi et al. unpubl.) were used. Thus, the energy available for different metabolic processes per gram of tissue (AFDW) in sexually mature individuals in this study was independent of their sizes.

The energy content measured (Figs. 3, 4 and 5) in this study is consistent with the range indicated in the literature (Brey et al. 1988).

In individuals of both sexes, the gonads contained mature gametes throughout the year, indicating partial spawning (Lomovasky et al. 2000). Coinciding with a decrease in gametic abundance in November (Lomovasky et al. 2000), declines in the relative condition index (Fig. 1) and energy content (Fig. 3) of FV were observed in both males and females. Although the decline in the energy content of FV cannot be unequivocally attributed to an increase in sexual activity, it should not be rejected as a likely cause as the proportion of lipid content in the gonads can be expected to decrease due to the emission of gametes. The increase in the relative condition index and the increase in the energy content during the summer months (December, January, February)

TABLE 2.

Tukey Test for unplanned comparisons among the energy content (kJ/g AFDW) of foot-visceral mass (FV), adductor muscle (M) and gills-mantle-siphons (GMS) for males and females of *E. exalbida* in Ushuaia Bay. Only months with significant differences are shown ($p < 0.05$).

	Males		Females	
	FV	M	FV	M
GMS	October December January May September	October January March May September	December	December January March July August September
M	March		November March September	

may be directly related to the increase in the number of mature gametes in these months (Morriconi et al. unpubl.). The higher surface temperatures in the sea and the greater availability of phytoplankton (Hernando, pers. comm.) are also present in these months suggesting that these environmental factors may be related to the maturation of gametes.

In March another drop in FV energy content was observed although it was not as pronounced as the decrease in November and was not significant for males. The March values are not related to changes in the gonads and may be related to variations in the energy content of the rest of the visceral mass or the foot.

No significant variation was found in the energy content of the adductor muscles (M) over time, suggesting that there are no changes in the proportion of the different biochemical components (proteins, lipids and carbohydrates) in this tissue. Nor were significant changes observed in the relative condition index over time, thus there is no evidence of changes in the muscular mass over time. Therefore, the adductor muscles do not fulfill the function of an energy reservoir as has been shown in pectinids (Sundet & Vahl 1981, Lucas 1996, Racotta et al. 1998).

The energy values were lower for GMS than for M and FV (except in November and March), remaining almost constant throughout the year. Similarly, no significant variation was found in the RCI for GMS over time.

Seasonal variation in temperature and the availability of food appear to be closely related to the energy available for growth and reproduction in different bivalve species, such as *Mytilus edulis* (Zandee et al. 1980, Sukhotin 1992, Smaal et al. 1997), *Aulacomya ater* (Griffiths & King 1979), *Placopecten magellanicus* (MacDonald & Thompson 1986), *Macoma balthica* (Beukema & De Bruin 1977), *Tapes philippinarum* (Mann 1979), *Cerastoderma edule* (Navarro et al. 1989, Smaal et al. 1997), *Meretrix meretrix* (Jayabal & Kalyani 1986). A similar relationship has been proposed for some Antarctic invertebrates (Clarke 1980).

In *E. exalbida* the variation detected in FV energy content and relative condition index during the experimental period is related to the reproductive status of the individuals, while the minimal variation in the energy content and relative condition index of M and GMS over the same period indicates a lack of energy transfer among organs and the absence of an energy reservoir. Thus, it follows that the energy necessary for different metabolic processes may be extracted directly from the food consumed.

BROODSTOCK MAINTENANCE AND EARLY GONADAL MATURATION OF *PHOLAS ORIENTALIS* (BIVALVIA: PHOLADIDAE)

E. T. MARASIGAN AND L. V. LAURETA

Institute of Aquaculture, College of Fisheries and Ocean Sciences, University of the Philippines in the Visayas, Miagao, Iloilo, Philippines 5023

ABSTRACT The angelwings, *Pholas orientalis* were maintained and conditioned in indoor tanks/basins. They showed high survival in both static system and flow-through system provided with a muddy sand substrate. Enhanced gonad development and earlier maturation were observed for angelwings fed a mixture of *Chaetoceros calcitrans* and *Tetraselmis suecica* at a rate of about 294 million cells per broodstock per day. Angelwings fed a mixture of two algal species spawned one to two months earlier than those fed one algal species. Results of the study demonstrated the hatchery potentials of angelwings.

KEY WORDS: *Pholas orientalis*, angelwings, broodstock, gonadal maturation

INTRODUCTION

Several years ago, the high demand for angelwings, *Pholas (Monothyra) orientalis* locally known as diwal in Panay and Negros Islands in Central Philippines resulted in the overexploitation of the species. The once dense beds are now almost devoid of this resource. Certain actions or interventions must be undertaken so that these areas would again become an important sustainable source of income for coastal fishermen.

The most active strategy in assisting improvement and rehabilitation of coastal mollusk fisheries is through stocking of artificially produced seedlings. This has been demonstrated in many eastern Asian maritime countries. In Japan, the production of *Haliotis* spp., *Paphia* spp., and *Pecten* sp. have increased tremendously (Honma 1980, Inoue 1984, Oshima 1984). In Taiwan, increased commercial productions were attained for shellfishes like *Meretrix lussoria*, *Gomphina veneriformes*, *Haliotis diversicolor* var. *supertexta*, *Solctellina diphos* and *Anadara granosa* (Chen & Yang 1979, Chen 1984, Ting 1984).

The Philippines lag behind in techniques of seed production and restocking of coastal areas to increase and sustain shellfish production compared to its neighboring countries. The main reason is the absence of molluscan hatchery, which is crucial and complementary to a rehabilitation program. We view that even hatchery-related studies are limited and mainly focused on oysters, mussels and scallops. Research on broodstock maintenance, spawning and nursery techniques for endemic bivalve species such as angelwings has not been given priority.

This study is the first effort to determine the hatchery potential of angelwings, *P. orientalis*. The feasibility of maintaining spawners of this species under laboratory conditions was evaluated. Further, we tested the influence of different types of algal species to bring about gonadal maturation and spawning in the laboratory.

MATERIALS AND METHOD

Spawner Maintenance

Adult angelwings (50–130 mm in shell length) were collected from the intertidal flats of Barotac Nuevo, Iloilo in Central Philippines (122°47′N and 10°55′E) that earlier was described by Laureta and Marasigan (2000). The specimens were scrubbed free of fouling organisms and debris prior to stocking.

Two holding techniques were evaluated for spawner maintenance in the laboratory: (a) static water system with aeration and without substrate sediments, and (b) flow-through water system with muddy sand substrate. All incoming water was filtered through sand. Three 40-l capacity circular white basins were used in the static system and three 30-l capacity fiberglass tanks were used in the flow-through system. Ten pieces of angelwings were placed in each container. The bivalves were laid horizontally in static systems and those in the flow-through systems were buried in the muddy sand substrate. During the two months of holding, the angelwings were fed either *Chaetoceros calcitrans*, *Tetraselmis suecica* or their combination. The algae were provided to the angelwings in the morning and afternoon at the rate of about 100 million cells per adult bivalve per feeding. The angelwings were reared in ambient light and temperature (range: 24–27°C) conditions of the laboratory with minimal disturbance. Survival of angelwings was evaluated after two months. Survival of the angelwings between the two holding techniques was compared using analysis of variance (Zar 1984).

Gonadal Development

Experimental Animals and Set-up

A total of 160 angelwings (>70 mm shell length) collected at five different dates in Barotac Nuevo were scrubbed free of fouling organisms and acclimated to feed on test phytoplankton species, *T. suecica* or *C. calcitrans*. Ten specimens were dissected and subjected to histological preparations to determine angelwings' stages of maturity and gametogenic cycles before the onset of the feeding experiment. Permanent mounts of the gonads were prepared following the modified Bell and Lightner (1989) method. The stages of gonadal development were described following stages for other clams (Rossell 1979, Jones 1981, Hesselman et al. 1989, Shafee & Daoudi 1991, Panurovsky & Yakovlev 1992) and the earlier description on reproductive stages of the angelwings by Laureta and Marasigan (2000). All ten specimens were found to be spent.

Fifteen cylindrical concrete tanks (diameter = 0.5 m; height = 0.75 m) with standpipes at the center filled with 0.3 m compact muddy sand and supplied with seawater to a maximum depth of 0.17 m by means of a flow-through water system, were used in this study. Each tank was stocked with ten angelwings by burying them in the muddy sand substrate. Water physico-chemical parameters in the culture tanks were monitored regularly. Water temperature was measured using mercury thermometer and salinity was monitored using Atago refractometer.

Experimental Treatments and Protocol

The study tested the effects of different algal food on the gonadal maturation of angelwings. The algae used were (a) *C. calcitrans*; (b) *T. succica*; and (c) combination (1:1) of the two algal species. Algae were given to the angelwings twice a day (morning and afternoon) at the rate of approximately 1.47×10^9 cells tank^{-1} feeding^{-1} or 2.94×10^9 cells tank^{-1} day^{-1}. Since 10 angelwings were stocked in each tank, each angelwing was presumed to receive 294 million cells day^{-1} during the first month. The daily provision of algal food for each tank remained the same throughout the experiment but algal food allotment for each angelwing increased every month because of decreased number of angelwings in each tank due to sacrifice sampling. Each of these feeding regimes was replicated five times and assigned at random to the 15 concrete tanks. Water flow was stopped for about two hours during feeding.

Evaluation of Gonadal Development

Gonad developments of angelwings fed algal diets were monitored every month for five months. One angelwing was extracted and dissected from each tank representing five replicate samples for each type of algal food. The histological preparation and method of determining gametogenic cycles as described earlier were used. The gonadal stages were: early active, late active, ripe, partially spent and spent. The percentage distribution of gonadal stages in each treatment diet was calculated. The gonad index was estimated by assigning rank for each stage modified from Wilson (1987) and King et al. (1989): 3 for early active, 4 for late active, 5 for ripe, 3 for partially spent, and 1 for spent. The gonad index of angelwings in each treatment diet per monthly observation is the sum of products of percentage of each stage (P_s) and its rank (R_s), giving value from 100 (all spent) to 500 (all ripe).

$$GI = P_s \times R_s$$

RESULTS

Spawner Maintenance

High survival of angelwings was obtained for broodstocks maintained in both static system with aeration (90 ± 0.0%) and the flow-through system with muddy sand substrate (93.3 ± 5.8%). There was no significant difference ($p > 0.05$) between the two systems. The spawners in both holding containers were agile and active as exhibited by constant protrusion of their siphons especially during feeding time.

Gonad Development

The percentage distribution of gonadal stages and the gonad index of angelwings after feeding different algal species in the laboratory are shown in Table 1 and Figure 1. The same table contains Laureta and Marasigan's (2000) percentage distribution of the combined gonadal stages of male and female angelwings collected at different sampling dates in their natural habitat for comparison purposes with the above. Gametogenesis started in angelwings indoor one month (Jan.) after the start of the experi-

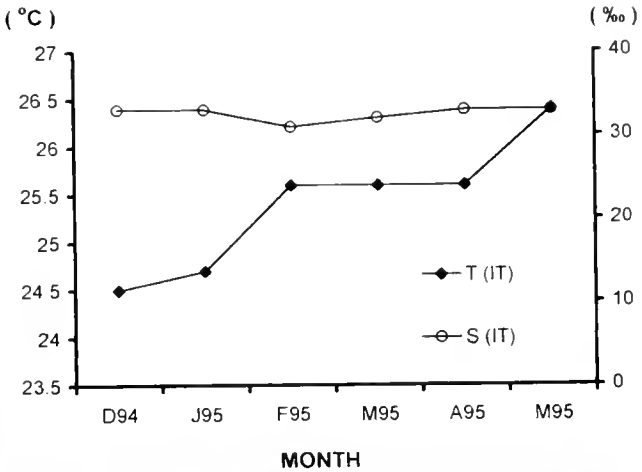

Figure 2. Variations in the temperature and salinity readings of the water in the indoor tanks from December 1994 to May 1995.

ment when 20% of the animals showed early active development. As the conditioning progressed from February through May, there was an increased percentage of mature angelwings that spawned later.

Angelwings fed combination of *T. suecica* and *C. calcitrans* showed faster gametogenesis, earlier maturation and spawning than angelwings fed one algal species. Sixty percent of the angelwings fed the mixed algal diet had ripe gonads by March while majority of angelwings fed either *C. calcitrans* or *T. suecica* did not attain the same gonadal stage until May. Angelwings fed combined algal species began spawning in April and continued in May while angelwings fed one algal species did not spawn until May. The highest histological gonad index of 460 was attained in March by those fed the combined species and in May by those fed single algal species

Angelwings in the natural habitat had advanced gonadal stages (Table 1) and higher gonad index (Fig. 1) compared to angelwings in indoor tanks at the start of the experiment. Although a similar proportion was ripe in the laboratory and the field in March, angelwings in indoor tanks spawned one month earlier (Apr.) than in natural habitat. Some of the angelwings fed combined algal species were already spent in May while in the natural population were only partially spent.

Water Physico-chemical Parameters

Water temperature in the culture tanks ranged from 24–26°C and salinity ranged from 31 to 33 (‰) (Fig. 2). No marked fluctuation was observed in the values of the parameters obtained during the culture period.

DISCUSSION

In this study, we reared and carried out gonadal maturation of angelwings in the laboratory. The similarity of survival rates between angelwings reared in circular basins without mud substrate and angelwings in tanks with mud substrate that accommodate the burrowing behavior of the species could be attributed to the minimal disturbance in both holding systems. Both systems minimized stressful conditions to the angelwings resulting in high survival and relatively faster gonadal development. Optimum holding conditions such as filtered seawater, gentle aeration, reduced water turbulence and ample supply of algal food enabled the bivalves to be active during the daytime for feeding as evidenced by continuous protrusion of their feeding siphons. In their natural habitat, the angelwings are subjected to environmental perturbations brought about by substrate instability caused by water turbulence, tidal fluctuations and fishing activities. In the field, we observed that angelwings in the coasts of Barotac Nuevo moved up and extended their siphons out of the sediment only during calm periods to feed. If dislodged by fishing i.e., trawls and dredges or turbulence due to typhoons, the angelwings could no longer get back to their burrows/homes (Ablan 1938, Laureta & Marasigan 2000). Further, we also noted that they were unable to create another burrow by themselves once exposed, thereby subjecting them either to physical stress such as water current and strong waves that usually damage and break their shells or predation.

Our results showed that angelwings could be conditioned to an earlier gametogenesis by feeding them high ration of single-cell algal diets. Earlier studies were successful in conditioning bivalves to sexual maturity through manipulation of temperature and increased food supply (Loosanoff & Davis 1963, Paon & Kenchington 1995). Apparently, the two types of algal food at a high ration fed twice a day per adult angelwing possibly satisfied the energy demanding process of gonadal maturation in shellfish (Sastry 1979). In an earlier study, Sastry (1968) reported that post-spawning adults of *Argopecten irradians* required an abundant food supply for initiation of gonadal growth and gametogenesis. The ration of 294 million cells/animal/day used in our study was higher than the highest feeding ration i.e., 67 million cells/animal/day of *Chaetoceros gracilis* and c-iso used by Villalaz (1994) to condition scallop, *Argopecten ventricosus*. The amount of algae fed to the angelwings approximated the recommended ration by Utting and Spencer (1991). However, our ration was apparently lower than the feeding ration totaling 400 million cells/day of *Thalassisiora pseudonana* fed to every broodstock of *Crassostrea gigas* by Muranaka and Lannan (1984).

The feeding mixed (1:1) algal species of *C. calcitrans* and *T. suecica* enhanced gonadal development and maturation of *P. orientalis*, and spawning which occurred one to two months earlier compared to individuals fed only one algal species diet. This may be attributed to the complementation of polyunsaturated fatty acids provided by two or more algal species as compared with a single algal species (Walne 1970, Helm 1977, Webb & Chu 1982, Gallardo et al. 1992). Robinson (1992) reported that mixing of differ-

ent algal species of unicellular algae as feed for broodstock oysters provide greater variation of fatty acid than from one species of algae.

Thus, the reduction of environmental stresses and the provision of combination of two species of single cell algae to angelwings reared indoor influenced its faster gonadal development and maturation compared to angelwings found in the natural habitat. Although we did not include the interaction of temperature and food supply, our results showed earlier maturation of laboratory reared angelwings despite the lower temperature compared to the temperature in the natural habitat (Laureta & Marasigan 2000). It appears that variation in water temperature ranging from 24 to 29°C was tolerable to the gonadal maturation of the angelwings due to high food concentration, which satisfied the angelwings requirements for development process. Earlier studies by MacDonald and Thompson (1985) also found that rapid tissue growth and shell increment of giant scallop *Placopecten magellanicus* were correlated to food availability rather than warmer temperature of the water column of Newfoundland and New Brunswick coasts. Our observations on the earlier or faster gonadal development of angelwings provided with high algal ration in the laboratory were in agreement with the observations of MacDonald and Thompson (1985) that growth of the giant scallops largely depended on reduction of nutritive stress and not necessarily influenced by warmer seawater temperature. Thus, it could be assumed that slower gonadal development and maturation of angelwings in the natural environment might be limited by the food supply.

ACKNOWLEDGMENTS

This study was supported by the Fisheries Sector Program-Bureau of Agricultural Research of the Philippine Department of Agriculture. We would like to thank the staff of Institute of Aquaculture, College of Fisheries and Ocean Sciences, University of the Philippines in the Visayas, for their moral support and technical assistance. We are grateful to Drs. Arnulfo Marasigan and Armando Tamse for reviewing and improving the manuscript.

THE REPRODUCTIVE CYCLE OF THE NEW ZEALAND VENUS CLAM *RUDITAPES LARGILLIERTI*

PAUL E. GRIBBEN,[1] ROBERT G. CREESE,[1] AND SIMON H. HOOKER[2]

[1]*School of Environmental and Marine Sciences and Leigh Marine Laboratory, University of Auckland, Private Bag 92019, Auckland, New Zealand;* [2]*National Institute of Water and Atmospheric Research Ltd (NIWA), PO Box 109695, Newmarket, Auckland, New Zealand*

ABSTRACT The reproductive cycle of the subtidal native New Zealand venerid clam *Ruditapes largilliertı* was studied over a 16-month period in the Whangateau Harbour, northeastern New Zealand. Gametogenic development between males and females was synchronous. *Ruditapes largillierti* was found to have an annual cycle, with gametogenesis beginning in autumn (March to May), and spawning over an extended period commencing in August and ending in early summer (December). Successful fertilization of gametes was verified by observations of settlement of postmetamorphosed spat onto spat catching bags suspended in the water column in the vicinity of the Whangateau Harbour at the end of the spawning season. The study population was dominated by large adults (45–55 mm shell length). Sex ratios between males and females were equal, and there was no evidence of hermaphroditism. The reproductive cycle described here is similar to other venerid and mesodesmid clams occurring in northern New Zealand.

KEY WORDS: clam, mollusca, *Ruditapes largilliertı*, reproduction, veneridae

INTRODUCTION

Although the export of cultured bivalves (made up almost exclusively of the Pacific oyster, *Crassostrea gigas*, and the green lip mussel, *Perna canaliculus*) is worth NZ$180m annually, the potential for culturing New Zealand clams for export remains relatively unexplored. In addition, there is known to be a significant amount of recreational harvesting, the extent of which is often underestimated (Kearney 1999). Venerid clams, in particular, are likely to play an important part in the growth of future shellfish industries because of the large and well established international markets for clam species from this family. At present, the only venus clam commercially harvested in New Zealand is the cockle, *Austrovenus stutchburyi*, for which a total of approximately 100t were exported in 1999 harvesting season (NZ Seafood Industry Council 2000). It is also the most commonly harvested recreational species. However, another species of venerid clam, *Ruditapes largillierti*, may be suitable for commercial exploitation (Maguire 1991) because of its similarity to the Manila clam, *Tapes philippinarum*, the only clam for which ubiquitous global markets exist (Manzi & Castagna 1989). *Ruditapes largillierti* was collected by indigenous (Maori) harvesters.

Investigation of the seasonal reproductive cycle of any marine bivalve is essential in developing a management strategy for a fishery, whether it is commercial or recreational (Shaw 1965, Manzi et al. 1985). The success of any hatchery-based commercial venture is also ultimately dependent on knowledge of reproductive cycles and an ability to spawn broodstock (Eversole 1989, Hooker & Creese 1995).

By following the progress of gonad and gamete production, researchers can determine the timing and duration of spawning events (Ropes & Stickney 1965, Corni et al. 1985, Hooker & Creese 1995). A knowledge of spawning periods is also needed for assessing larval abundance (Ropes & Stickney 1965), predicting periods of annual recruitment (Keck et al. 1975, Manzi et al. 1985) and for interpreting growth rates and mortality data (Keck et al. 1975, Baron 1992). Ultimately, all these factors influence the distribution and abundance of juvenile and adult populations (Shaw 1965, Hooker & Creese 1995).

Histological techniques are the most commonly applied methods for determining the reproductive cycle of clams. Although they can be expensive and time consuming, histological techniques are the only reliable way of documenting gametogenic processes (e.g., Shaw 1962 and Shaw 1965, Ropes & Stickney 1965, Adachi 1979, Eversole et al. 1980, Mann 1982, Robinson & Breese 1982, Ropes et al. 1984, Manzi et al. 1985, Rosenblum & Niesen 1985, Knaub & Eversole 1988, Rowell et al. 1990, Ponurovsky & Yakovlev 1992, Hooker & Creese 1995). Histological sections can be used for both qualitative assessment and quantitative analysis of gamete development, typically using measures of oocyte size. Eversole (1989) contends that comparisons of gametogenic cycles among species would be easier if more quantitative measures of gonadal development were used (e.g., Kennedy & Battle 1964, Heffernan & Walker 1989). In the present study, both qualitative and quantitative measures were used to assess gonad development of *R. largillierti* in a northeastern New Zealand harbor.

The information presented in this paper provides the first description of the reproductive cycle of *R. largillierti* in New Zealand using both qualitative and quantitative methods, and explores whether or not the patterns observed are part of an annual cycle.

MATERIALS AND METHODS

The reproductive cycle of *R. largillierti* in the Whangateau Harbour (northeastern coast of New Zealand's North Island; Fig. 1) was documented using histological analysis of samples collected monthly from October 1996 to October 1997. An additional sample was collected in January 1998. Thirty adult clams were collected subtidally in 3–7 m of water each month using SCUBA, and transported to the Leigh Marine Laboratory, approximately 4 km from the Whangateau Harbour (Fig. 1). Clams were processed within two hours of arriving at the laboratory.

The length (anterior-posterior axis) of each clam was measured to the nearest millimeter using vernier calipers. Following this the shell was pried open using a small knife and the visceral mass removed and fixed in Bouin's solution. After allowing five days for the sample to harden the visceral mass was extracted, and the siphons, mantle and gills removed. The remaining visceral mass, with associated gonad, gut and attached foot, was then placed in a histological cassette and preserved in 70% ethanol.

Samples were dehydrated using a graded ethanol series, blocked in paraffin wax and sectioned at 7 μm. Three longitudinal

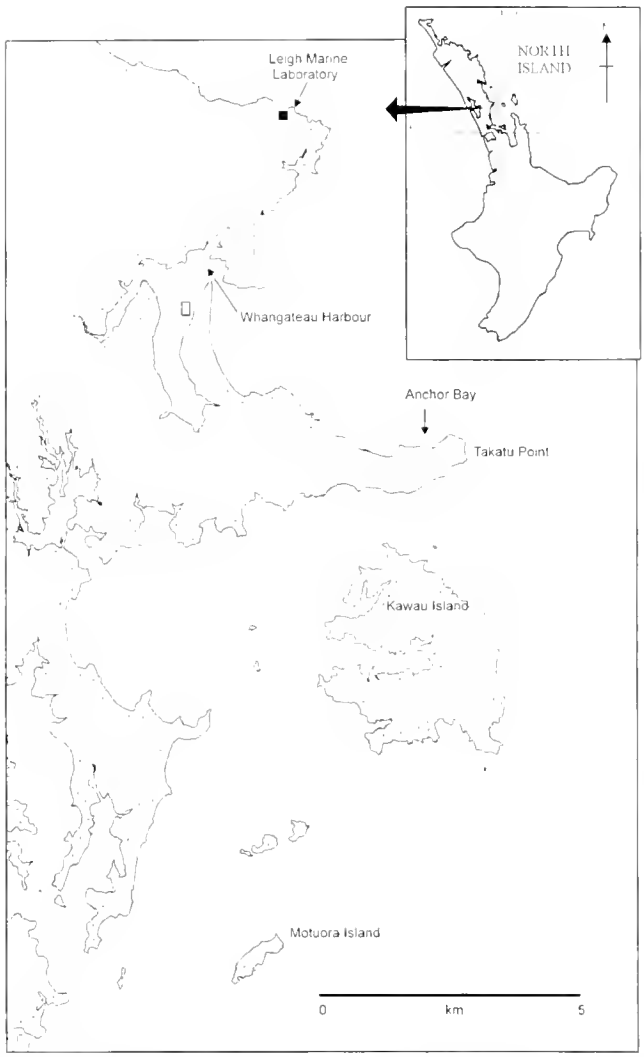

Figure 1. Map showing the location of the Whangateau Harbour, where clams were collected for reproductive analysis from October 1996 to January 1998, and the location of spat catching bags placed at Motuora Island and Anchor Bay, from August 1997 to January 1998. Scale bar = 3 km.

sections (along the anterior-posterior axis) were taken from each sample. All sections were stained using Haematoxylin and counterstained with Eosin. The histologically prepared slides were then examined using a compound microscope at ×40, ×100 and ×400 magnification. Gonads from both male and female clams were placed into five qualitative categories adapted from Porter (1964), Keck et al. (1975) and Ropes (1968): early active, late active, ripe, partially spawned and spent (Table 1; Fig. 2A–J). The gonadal state of each clam was described as one of the five stages based on the most dominant stage present in 10 randomly selected follicles from each sample.

The sex of each clam was determined from microscopic examination of the histological slides. Clams were deemed sexually mature if any mature gametes were present. A Chi-squared goodness of fit test ($\alpha = 0.05$) was used to test the hypothesis that there was an equal representation of males and females in this population. Clams were also examined for any evidence of hermaphroditism as some species of venerid clams are known to have male and female gametes co-occurring within the same individual.

Monthly mean oocyte diameters were determined using video image analysis (Mocha Image Analysis 1.2; Jandel Corp. 1994) in order to validate the gametogenic development of female clams. The diameters of all oocytes within three haphazardly selected follicles from each of the three slides were measured for 10 female clams sampled in each month. Only oocytes with visible nuclei were measured.

Interpretation of spawning events from histological analysis is based on the qualitative assessment of gonad staging. In order to validate spawning events deduced from the histological stagings, a spat catching experiment was established in Anchor Bay (174°50.5′E, 36°30′S) approximately 4 km from the Whangateau Harbour, and adjacent to Motuora Island (174°48′E, 36°30′S), approximately 15 km from the Whangateau Harbour (Fig. 1). Anchor Bay was chosen as water exiting the Whangateau Harbour circulates through this area (Parr 1993). Motuora Island was chosen as it is known to be a sink for bivalve larvae (Morrison 1998). It was not possible to put spat catching bags in the Whangateau Harbour because of the strong tidal currents and the high recreational use of the harbor.

Three 25 m drop lines were anchored to the seafloor in each region. Three 0.5 m^2 replicate mesh bags were placed at intervals of 5 m, 10 m and 15 m above the seafloor on each drop line by SCUBA in August 1997. The meshbags were collected and replaced in September 1997 and October 1997. The final set of bags was removed from the lines in January 1998 and not replaced. All bags were transported back to the laboratory and individually searched for the presence of newly settled clams.

RESULTS

Reproductive Cycle

Despite slight differences in gamete development between males and females, the reproductive development of both male and female clams followed similar patterns (Fig. 3a, b) which appeared to be related to changes in sea-surface temperatures (Fig. 3c). During 1997, gametogenic development began in March/April (early autumn): a period of decreasing water temperatures. Gametes continued to develop through August and September (winter) with ripe individuals first observed in the coldest winter months. Spawning began in August with a small number of both male (20%) and female (7%) gonads appearing partially spent. Spawning activity increased as sea-surface temperatures continued to rise. By October 1997, 70% of males and 82% of females appeared in a partially spent or spent condition. This pattern was also observed a year earlier in October 1996, although the spawning event seems to be stronger with all clams in either a spent or partially spent condition (Fig. 3a, b). During the 1996/1997 spawning period, all clams were completely spent by December 1996. Although clams were not sampled in December 1997, this pattern appears to be repeated during 1997/1998 with all clams having spent gonads by January 1998.

Oocyte Development

The mean monthly diameter of oocytes ranged from 21.3 μm (February 1997) to 31.9 μm (March 1997) (Fig. 4). The peak value in March 1997 was due to the small number of residual oocytes that hadn't yet been resorbed. From October 1996 to January 1998 mean monthly diameters alternated regularly between high and low values. Although there does not appear to be a strong rela-

TABLE 1.

Criteria used to stage histologically prepared slides. Adapted from Porter (1964), Keck et al. (1974) and Ropes (1968).

Stage	Males	Females
Early active	Follicle walls thick, lined with a thick layer of spermatogonia occupying up to a third of follicle area. Spermatocytes and spermatids develop in the middle of the follicle. Spermatozoa, with tails pointing into the lumen, often occupy the center of the follicle. Gonad volume is small.	Follicle walls thick, often contracted. A lot of ovogenic activity with many oogonia and primary oocytes attached to the follicle walls. Mature oocytes and ova present. Gonad volume is small. There is often a lot of connective tissue visible within the gonad.
Late active	Follicle walls are thin. Spermatogonia restricted to lining the follicle walls. Follicle dominated by dense areas of spermatids and spermatocytes. Spermatozoa more abundant than early active.	Follicle walls are not as thick. There are a lot more ova and mature oocytes than in the early active stage, often attached to the follicle wall by a thin stalk. There are fewer primary oocytes. Mature oocytes are often rectangular or polygonal in shape.
Ripe	Spermatogonia as for late active. Follicle dominated by very dense spermatozoa with tails pointing into the lumen. Spermatids and spermatozoa occupy less follicle volume. Gametes occupy nearly all the gonad volume.	Follicle walls are thin and full of ova often lying free in the lumen. There is little ovogenic activity within the follicle except for a few mature oocytes. Ova are usually spherical in shape.
Partially spawned	Spermatozoa still occur in the follicle but with large gaps. Center of the lumen often appears empty. Spermatogonia intrude further into the follicle although no more abundant than in the previous stage. Spermatids and spermatocytes less dense but still fairly common.	Follicles are large with walls that are very thin and often ruptured. There are usually large spaces within the lumen, although free ova are still frequent within lumen of the follicle. There are still mature oocytes present.
Spent	Follicle walls are thickened. Few spermatogonia still present, with few unspawned spermatids, spermatocytes and spermatozoa still remaining. Gametes occupy very little of the gonad volume.	Spawned: The follicle is essentially empty with a few ova still free in the lumen. Follicle walls may be contracted and thickened with connective tissue.

tionship between stage of reproductive development and mean monthly oocyte diameter, peak mean oocyte values occurred during June 1997, a month dominated by developing late active oocytes, and September 1997, which is dominated by ripe and late active oocytes.

Analysis of the monthly frequency histograms for oocyte diameters indicates egg size ranged from 10 to 27 μm and that a broad range of egg sizes was present in all months sampled (Fig. 5). Again, there does not appear to be a strong association between the relative frequencies of egg diameters in each mode and stage of reproductive development.

Sex-Ratio

Adults collected during monthly sampling ranged in size from 29–58 mm shell length, and all could be sexed. The Chi-squared test performed on the monthly and total number of males and females sampled failed to detect any significant difference from a ratio of 1:1 (Table 2). However, the sex ratio of the 10 clams collected ≤35 mm (3 males and 7 females) was 1:2.33.

Size at Sexual Maturity

Length (longest anterior-posterior distance) was used to assess size-at-sexual maturity. All clams collected were mature. Males and females had almost identical size ranges and mean shell lengths in all months sampled (Table 3). Males ranged in size from 29–57 mm and females ranged from 29–58 mm (Table 3). The mean monthly length of males ranged from 44.3 (±7.51) to 51.3 (±1.5) and from 44.0 (±9.4) to 51.1 (±2.9) for females.

Occurrence of Newly Metamorphosed Juveniles

Twelve *R. largillierti* spat were recovered from the series of meshbags retrieved from Anchor Bay in January 1998. These ranged in size from 0.5–1.5 mm in length. The presence of *R. largillierti* spat at this time correlates well with the spawning period evident from the histological stagings in the 4 months prior to January 1998. However, no post-metamorphic clams were found on any of the bags recovered from Motuora Island.

DISCUSSION

Temperature is often regarded as the main factor determining the general patterns of reproductive development and spawning. Indeed, many species experience latitudinal gradients in the timing of reproductive development and spawning events, and also in the number of spawning events associated with changes of temperature (e.g., Keck et al. 1975, Eversole 1989, Heffernan et al. 1989). As with other species of clams, the reproductive cycle of *R. largillierti* in the Whangateau Harbour appears correlated to changes in sea-surface temperature. Gamete development began in autumn (March–April) as seawater temperatures started falling, with ripe individuals first present when temperatures were at their lowest during July. Spawning commenced in August as seawater temperatures began rising, although the majority of spawning appeared to occur during the months of October and November. Paturusi (1994) found a similar pattern of reproductive development for *R. largillierti* in Georges Bay, Tasmania. The native geoduck, *Panopea zelandica*, collected from the Coromandel Peninsula from June 1999 to March 2001 also went through a similar reproductive cycle to that of *R. largillierti*, with spawning beginning in early spring and ending in early summer (Gribben unpub. data). Spawning of the pipi, *Paphies australis* (Hooker & Creese 1995), and the tuatua, *P. subtriangulata* (Grant & Creese 1995), in the Whangateau Harbour also began in early spring, however, it continued right through summer.

Although the reproductive cycle was correlated to sea-surface temperatures, low temperatures during the winter, particularly in

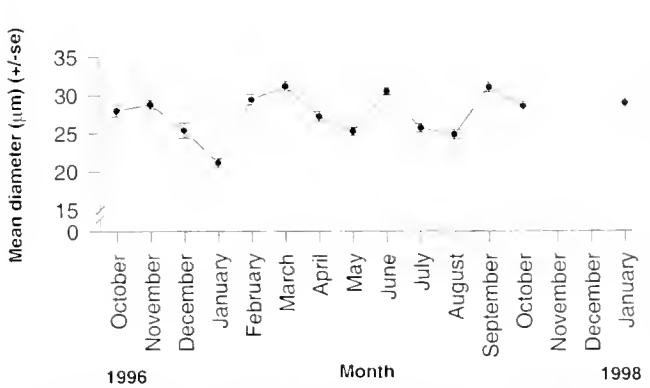

Figure 4. Mean monthly oocyte diameters (±se) from histological analysis of female *R. largillierti* (October 1996–January 1998); n = 10–17 individuals.

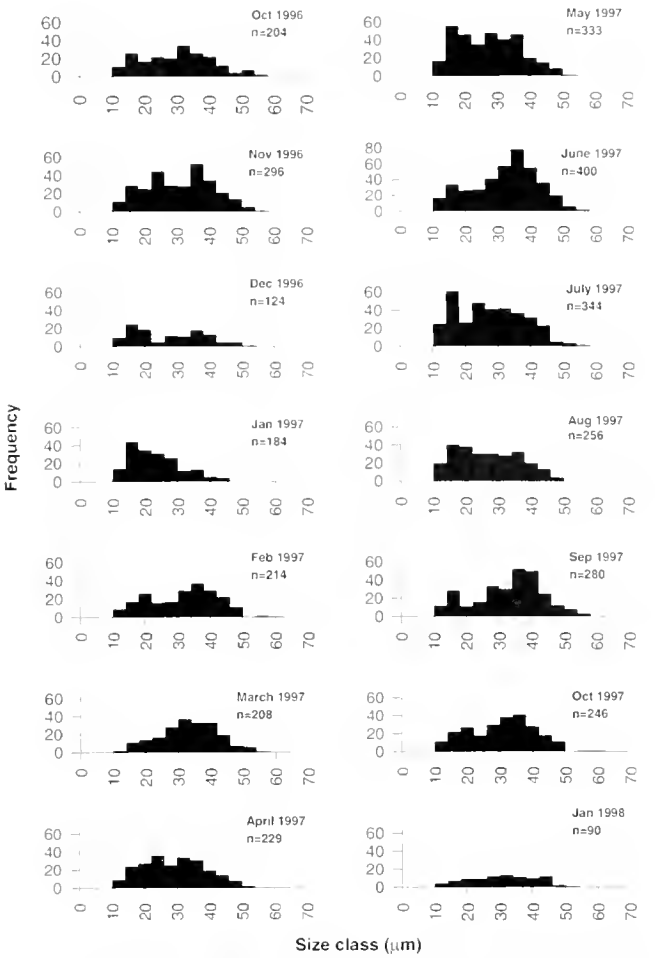

Figure 5. Frequency histograms for all oocyte diameters measured from nine haphazardly selected follicles for each of 10 females from each monthly sample collected for histological analysis (October 1996–January 1998).

August, do not appear to restrict development, as early active, late active and ripe clams were evident as early as July, when water temperatures were at their lowest (13°C; Fig. 3c). *Ruditapes largillierti* occurs throughout New Zealand's waters with its distribution extending to some sub-Antarctic islands (Powell 1979). The Whangateau Harbour is near the northern limit of its distribution. If *R. largillierti* is a species more suited to cooler temperatures, then a period of inactivity following spawning, such as that which occurred from December to March after the 1996/1997 spawning period, may be a result of high summer water temperatures restricting gametogenic development. Early male development, however, commenced in March, soon after the maximum average monthly water temperatures were recorded.

In gonochoristic species, such as the majority of venerid clams, the synchronous development and spawning of gametes in local populations is essential for successful fertilization to occur (Eversole 1989). The fact that small numbers of post-metamorphic clams were found on spat catching bags in Anchor Bay, confirms that spawning and successful fertilization occurred prior to January 1998. Despite successful fertilization occurring, there were slight differences in the timing and duration of development, maturation and spawning between the two sexes. Female reproductive development began later than in males, possibly because the energetic

costs of reproduction are often greater for females than males (Ropes et al. 1984). Therefore, following a major spawning event, females may need to accumulate greater energy reserves relative to males in order to produce gametes once the costs of growth and respiration have been met. However, female gametes develop more quickly through the early active to the late active stage, whereas males develop steadily with a long period dominated by the early active stage of the gametogenic cycle. A pattern of similar overall development with subtle differences between males and females is well documented for many species of clams (e.g., Porter 1974, Manzi et al. 1985, Corni et al. 1985, Hefferman et al. 1989, Hesselman et al. 1989, Rowell et al. 1990, Sbrenna & Campioni 1994).

The appearance of a large number of spawned and partially spawned clams in both October 1996 and 1997 suggests that reproduction followed an annual cycle. Although samples were not collected during November and December 1997, by January 1998 all clams had completely spawned. This was also observed in January 1997. The small number of unspawned late active and ripe individuals that occurred in October 1997 but not in October 1996 are most likely due to inter-annual variability in reproductive development.

Eversole (1989) suggests that comparisons of reproductive development among species would be easier if more quantitative measures of gonadal development were used. Both Kanti et al. (1993) and Villalejo-Fuerte et al. (1996) found a close relationship between oocyte diameters and the gametogenic cycle in *Spisula solidissima similis* in California, and the cockle, *Laevicardium elatum*, in Mexico, respectively. Xie and Burnell (1994) also found that oocyte frequency histograms appeared to support qualitative data on reproductive cycles for both *Tapes philippinarum* and *T. decussatus* on the south coast of Ireland. In general, studies that have employed quantitative analyses indicate that periods of maturation and spawning tend to coincide with maximum oocyte diameter values. However, the association between oocyte diameters and the remainder of the reproductive cycle (excluding spawning events) is unclear (e.g., Eversole et al. 1980, Heffernan & Walker 1989, Hesselman et al. 1989). This also appears true for *R. largillierti*. Peak mean oocyte diameters are associated with months containing eggs in later developmental stages (e.g., October and November 1996, and June and September 1997), and troughs with the presence of higher numbers of primary oocytes (e.g., January, May and August 1997). Although monthly mean oocyte diameters support the findings of qualitative stagings, the patterns are not strong enough to be used on their own as a quantitative indicator of gonad state. Much of this can be attributed to the inherent variability in gonadal state both within and among individuals collected from the same sample, evidenced from the large size range of oocyte diameters that exists for each monthly sample (Fig. 5). Several authors have tried to resolve this problem by reducing the number of stages used to assess gonadal state (e.g., Keck et al. 1975, Eversole et al. 1980).

With the exception of the hardshell clam, *Mercenaria mercenaria*, sex ratios in venerid clams rarely differ significantly from a ratio of 1:1 (Eversole 1989); *M. mercenaria* is protandric with males dominating juvenile stages until sexual maturity is reached. However, the sex-ratios of adults are equal. Overall, this study showed equal numbers of adult male and female clams. However, the restricted size range sampled (only clams over 29 mm) excludes investigation of sex-ratios of juveniles. The sex-ratio of 1 male to 2.33 female clams in the lower end of the sample (29–35 mm) indicates that the ratio may be quite different for smaller clams. However, this is probably more a reflection of the small sample size rather than an indicator of any real trend. The lack of small size classes also makes it difficult to determine the size at which *R. largillierti* reaches sexual maturity. However, all clams between 29–35 mm in length were mature and contained gametes. Analysis of tag and recapture data and experimental growth rates (Gribben 1998) suggest that *R. largillierti* 29–35 mm in length are in their second year of growth. It is likely that sexual maturity is reached between 25–28 mm, as clams grown under experimental culture conditions grew to a maximum size of 24 mm in one year and contained no gametes (Gribben 1998).

The commercial culture of venerid clams is well developed overseas with several species (e.g., *M. mercenaria* and *T. philippinarum*) relying on the production of hatchery reared spat (Manzi

TABLE 3.

Range and mean length (±s.d.) (mm) for male and female *R. largillierti* collected monthly (n = 30) from the Whangateau Harbour, from October 1996 to January 1997.

Month	Male Range (mm)	Female Range (mm)	Males Mean Length (±s.d.) (mm)	Females Mean Length (±s.d.) (mm)
October 1996	29–54	32–56	44.3 (±7.51)	44.0 (±9.4)
November 1996	45–54	46–57	50.7 (±2.7)	51.1 (±2.9)
December 1996	46–53	43–54	50.2 (±2.7)	50.8 (±3.28)
January 1997	48–53	45–52	51.3 (±1.5)	50.2 (±2.0)
February 1997	48–57	39–53	48.6 (±5.3)	47.1 (±4.4)
March 1997	33–53	40–53	46.9 (±5.9)	46.6 (±4.4)
April 1997	34–55	39–58	47.3 (±6.7)	47.6 (±5.7)
May 1997	37–54	43–52	48.2 (±4.9)	48.5 (±3.0)
June 1997	34–53	43–54	47.3 (±4.8)	49.3 (±2.9)
July 1997	43–53	42–54	49 (±2.7)	48.6 (±3.2)
August 1997	32–55	32–54	48.5 (±5.3)	47.5 (±6.3)
September 1997	36–56	42–55	46.9 (±4.7)	46.9 (±3.9)
October 1997	32–53	29–53	44.9 (±5.1)	45.5 (±4.6)
January 1998	35–56	41–54	48.3 (±5.4)	48.5 (±6.2)

& Castagna 1989). Kent et al. (1999) have successfully produced an ongrown hatchery-reared *R. largillierti* spat in Australia. Given that *R. largillierti* spat can be produced in a hatchery, and Gribben (1998) has achieved good growth rates ongrowing juvenile *R. largillierti* intertidally and subtidally in mesh bags on racks, suggests that this species may be amenable to aquaculture.

The results from our research suggest *R. largillierti* in the Whangateau Harbour are ripest from early spring to early summer. Collecting broodstock during this time will maximize egg viability and fertilization success: two of the most important issues facing aquaculturists attempting to produce commercial quantities of spat.

ACKNOWLEDGMENTS

This study was supported by a Graduate Research in Industry Foundation scholarship, made possible with the help of Jim Dollimbre and Jon Nicholson. Many thanks to Beryl Davy for her invaluable instruction and guidance with the preparation of histological samples. Thanks also to the numerous people at the Leigh Marine Laboratory who assisted with collecting samples from the Whangateau Harbour. This research formed part of a MSc thesis in Marine Science from the University of Auckland.

STOCK ASSESSMENT FOR VENUS CLAM, *CHIONE CALIFORNIENSIS* (BRODERIP, 1835) IN ENSENADA DE LA PAZ, BAJA CALIFORNIA SUR, MÉXICO

HUMBERTO WRIGHT-LÓPEZ,[1] FRANCISCO ARREGUÍN-SÁNCHEZ,[1] FEDERICO GARCÍA-DOMÍNGUEZ,[1] OSCAR HOLGUÍN-QUIÑONEZ,[1] AND DANIEL PRADO-ANCONA[2]

[1]*Centro Interdisciplinario de Ciencias Marinas del IPN, Apartado Postal 592, 23000, La Paz, Baja California Sur, México;* [2]*Centro de Investigaciones Biológicas del Noroeste, S. C., Apartado Postal 128, 23000, La Paz, Baja California Sur, México*

ABSTRACT The stock assessment of the venus clam *Chione californiensis* from Ensenada de La Paz, Baja California Sur, México was made based on survey and commercial catch data. Stock is exploited twice a year, February to early April, and September and October. Elefan I was used to estimate growth parameters of the von Bertalanffy equation. Age structure was computed from a length-age key probability matrix to assign age to length. Natural mortality varying with age and time was estimated using an algorithm based on the Leslie transition matrix and data from unexploited periods. Catchability-at-age was also estimated through an analogous algorithm, but using data for exploited periods. Both algorithms have a numerical solution which uses a least square as fitting criterion. A modified age-structured virtual population analysis (VPA), accounting fishing-effort data, was used to estimate fishing mortality and stock size. Higher values for harvest rate (HR) and fishing mortality (F) occurred during the second fishing period, reaching values of HR = 70%. This is particularly important because it coincides with spawning and recruitment seasons such that exploitation is strongly impacting stock size. Our results also offer an explanation about why clam stocks have been depleted or collapsed.

KEY WORDS: stock assessment, venus clam, *Chione californiensis*, natural mortality-at-age, catchability-at-age, stock depletion

INTRODUCTION

Along the southern coasts of the Peninsula of Baja California there are a variety of clam species that have been exploited for many years. In 1995 the total yield amounted to 9,140 tons, representing 70% of the total clams caught in Mexico. Eight species of Veneridae are exploited in Baja California Sur as target species: *Tivela stultorum* (almeja pismo and pismo clam), *Megapitaria squalida* (almeja chocolata and squalid callista), *M. aurantica* (almeja chocolata roja and golden callista), *Dosinia ponderosa* (almeja blanca and ponderous dosinia), *Peryglipta multicostata* (almeja roñosa de risco and many-ridged venus), *Chione undatela* (frilled californian venus), *C. gnidia* (ornate venus), and *C. californiensis* (almeja roñosa and californian venus clam) (Holguín 1976, Baqueiro et al. 1982, Baqueiro & Guajardo 1984, Prado-Ancona 1998).

The venus clam *C. californiensis* is an intertidal bivalve distributed from the coastline up to 69 m depth, in sandy bottoms. In Ensenada de La Paz (Fig. 1), the highest densities of about 48 clams m^{-2} have been observed in the upper portion of the mid-intertidal area between 0 and 3 m deep (García-Domínguez et al. 1994). Distribution is determined by the type of bottom, with the clam living on sandy or rocky-sandy bottoms (García-Domínguez 1991). Catch takes place in shallow waters during low tides, when fishermen collect clams by hand or using some dredging instruments. In several locations along the southern Peninsula of Baja California, clam stocks have decreased and some have disappeared almost completely (García-Domínguez 1991). There are two apparent reasons for this: they have been overexploited because of their high vulnerability and fisheries operate under an open access scheme, or because of bottom disturbances caused by human activities along the coasts. For both, the absence of knowledge to support appropriate management measures has been an additional problem. In this paper, the stock assessment of a venus clam *C. californiensis* in Ensenada de La Paz is developed as a contribution to the knowledge of the population dynamics. Some management aspects are discussed.

MATERIAL AND METHODS

Ensenada de La Paz has an area of 45 km^2, with a communication with Bahia de La Paz through a channel 1.5 km long and 4 km wide (Fig. 1). The stock we studied is located in a place known as Las Palmitas (24°10′N and 110°24′W). Samples were taken from July 29, 1988 to September 20, 1989 on a transect perpendicular to the shoreline, passing across the high clam-density area. Venus clams were collected every 25 m along the transect, where 20 cm^3 of sediment (a square of 1 m per side and a depth of 20 cm) was taken and sieved through a 1-mm mesh. The total length of the clams was measured with a precision of 0.01 mm within a range of 4 to 43.5 mm. A number of clams were also weighed to compute the length-weight relationship.

The venus clam stock is exploited twice a year, within the period of time we studied, September to October 1988 and February to April 1989. Catch records were collected from Sepesca (1988, 1989) for these periods.

Growth

The ELEFAN I method (Pauly and David 1981, Pauly 1987) was used to estimate the parameters of the von Bertalanffy growth equation (VBGE). For this, length frequency distributions were grouped in 3-mm length-class sizes.

Age Structure

Age structure was estimated as follows. First, we selected the Gaussian components in the length-frequency distributions, using the Bhattacharya (1967) method, to obtain mean length and variance for some age groups. Then a function of how variance of the mean length-at-age group changes with relative age was fitted. The relative age from modal lengths was estimated according to the VBGE. With this function we were able to estimate mean and variance for all ages in the stock. Normal distributions representing age groups were converted to a standardized normal distribution $N(0,\sigma^2)$ to obtain a length-age key in terms of probability, which

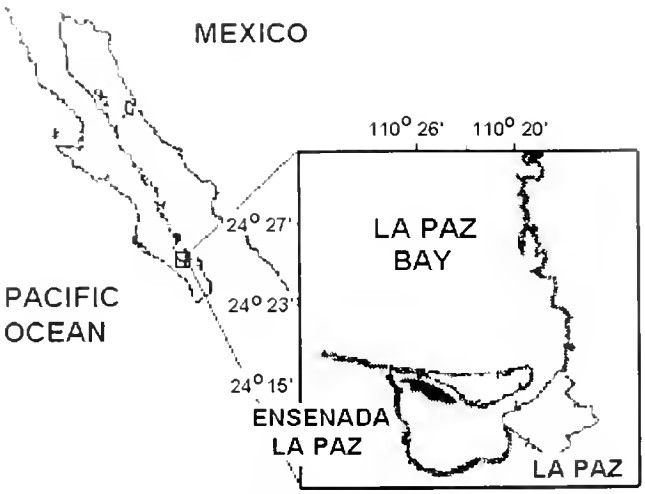

Figure 1. Location of Ensenada de La Paz in Baja California Sur, Mexico.

was used to assign the probability for a given length to belong to a given age. Here, we named it the length-age key probability matrix, PM. Then, the product of the transposed vector of a length frequency distribution and the PM resulted in an age-structured vector.

Natural Mortality-at-Length

Natural mortality, M, was estimated through an iterative process based in the transition matrix following Arreguín-Sánchez et al. (2000). This procedure computes M varying with length and time, and is described by the relationship

$$N(\ell, t + \Delta t) = \Sigma_k[G(\ell, k) \times S(k)] \times N(k, t) \quad (1)$$

where N represents the length structure vectors, in this case expressed as stock density, and k and ℓ represent successive length classes. G is the growth matrix whose elements represent growth probabilities per length class according to the VBGE (following Shepherd 1987). S is the survival matrix, whose elements represent an average survival estimate of the k length class, and t represents time. Because the venus clam is a relatively short-lived species, age was measured in months; Δt represents time between samples. When $\Delta t \neq 1$ mo, time was measured as a proportion, taking the month as a unit. Elements in the survival matrix are expressed as $S(k) = \exp(-M)\Delta t$ when there is no fishing, and $S(k) = \exp(-(M + F))\ \Delta t$ when exploitation is being done, with F being the instantaneous rate of fishing mortality.

Because exploitation occurred in two periods, September and October and February to March, Eq. 1 was iteratively solved for those months when there was no fishing. For this, the growth matrix was computed using the estimated parameters of the VBGE; $N(k, t)$ and $N(\ell, t + \Delta t)$ are known, and M was varied. Fitting process used a least squares algorithm with the form

$$\text{MIN} \sum_{\ell}^{n} (N_{obs}(\ell, t + \Delta t) - N_{est}(\ell, t = \Delta t))^2 \quad (2)$$

Catchability-at-Length

The average yield per fishermen in a regular fishing season is about 200 clams per hour, corresponding to an average density of 33.5 clams m^{-2} in a searching area of 10 km^2. This information provides an index of fishing effort at time t, E_t. Catchability was estimated following Arreguín-Sánchez (1996) and Arreguín-Sánchez and Pitcher (1999), whose method is also based on Eq. 1, but using catch per unit effort length frequency data for the exploited periods, but giving the M-at-length values estimated as above. In such case, survival is expressed as $s(k) = \exp - [M(k, t) + q(k, t)f(t)]$, with q and f the catchability coefficient and fishing effort, respectively. Then, iterations were done varying catchability coefficients in elements of the survival matrix. The fitting process also used a least-square algorithm as in Eq. 2.

M-at-length and catchability-at-length were easily transformed to age by computing relative ages through the VBGE.

Stock Size and Fishing Mortality

Stock size was estimated through the use of the Gulland (1965) and Murphy (1965) methods as follows:

$$\text{Let} \quad C_{a,t} = N_{a,t} \times E_{a,t} \quad (3a)$$

where

$$N_{a,t} = N_{a,t-1} \times \exp - (M_{a,t} + F_{a,t}) \quad (3b)$$

which represents the stock survival process for two successive ages. $E_{a,t}$ represents the exploitation rate-at-age, with a the index for age, and $E_{a,t}$ expressed by

$$E_{a,t} = \left(\frac{F_{a,t}}{(M_{a,t} + F_{a,t})}\right)\{1 - \exp(-[M_{a,t} + F_{a,t}])\} \quad (4)$$

The ratio of catch at successive times is represented by

$$\frac{C_{a}+1, t+1}{C_{a,t}} = R_{a,t} = \frac{\{\exp[-(M_{a,t} + F_{a,t}])\} \times E_{a+1, t+1}}{E_{a,t}} \quad (5)$$

Given M_t and F_t, a forward solution can be obtained for two situations.

$$\text{For } E_{a,t} \neq 0, \quad E_{a+1,t+1} = R_{a,t} \times E_{a,t} \times \exp(-[M_{a,t} + F_{a,t}]) \quad (6a)$$

and

$$\text{For } E_{a,t} = 0, \quad E_{a+1,t+1} = R_{a-x,t-x} \times E_{a-x,t-x} \times \exp\{-([t-x]M_{a-x,t-x} + F_{a-x,t-x})\} \quad (6b)$$

Where $(a - x)$ and $(t - x)$ represent age and time between the exploited age at time t and the nonexploited age at time x.

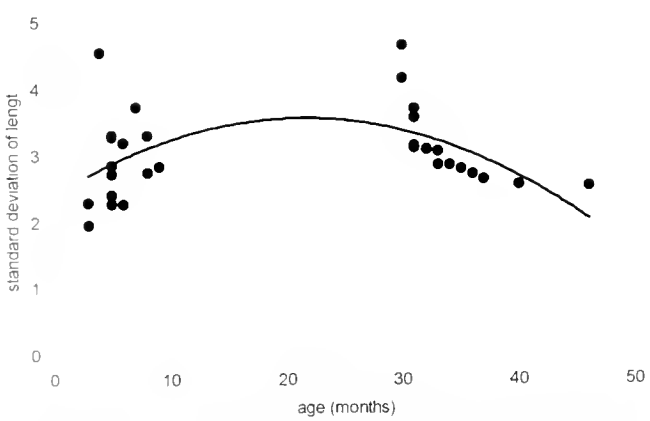

Figure 2. Standard deviation(s) of length (millimeter) per age group, as a function of age (months) for the venus clam *C. californiensis* from Ensenada de La Paz, Mexico.

Once estimates for $E_{a,t}$ are obtained, an estimate for $N_{a,t}$ for the last age group can be obtained from Eq. 3a, and for other age groups from Eq. 3b. In this case, the fitting process was a least-squares algorithm based on catch with the form

$$\text{MIN} \sum_{a=1}^{a_{max}} [C_{obs}(a,t+\Delta t) - C_{est}(a,t+\Delta t)] \quad (7)$$

where C_{obs} = observed catch and C_{est} = estimated catch, which was obtained from Eq. 3 (with estimated values for $N_{a,t}$ and $E_{a,t}$).

Murphy (1965) suggested a forward solution to a catch equation in a cohort analysis; for this, an estimate of recruits should be available. Here, recruits per month were estimated from survey and commercial catch as follows. During catch periods, Eq. 6a was applied using a seed value for $F_{a,t}$ as in the virtual population analysis (Gulland 1965, Gulland 1983, Pope 1972, Pope & Shepherd 1982, Pope & Shepherd 1985), and using Eq. 7 as the fitting criterion. Results were compared with survey abundance data, and the average ratio was used to estimate recruitment over those months with no fishing. Once recruits were obtained, the stock assessment process, following Murphy's algorithm, was developed.

RESULTS

Growth

Growth parameters for the von Bertalanffy growth equation were $L\infty$ = 48.2 mm, K = 0.735 year^{-1}, and to = −0.64 years. Parameters for the length (millimeters) - weight (grams) relationship were a = 0.00016 and the slope b = 3.234. These estimates resulted in a value for asymptotic weight of $W\infty$ = 46 g.

Age Structure

Because the venus clam is a relatively short-lived species, with a life span of around 4 y (Castro-Ortiz & García-Domínguez 1993), we decided to express age in month units. Once Gaussian components were obtained from length-frequency data, a plot representing variance per age group as a function of age was approached as a parabolic function (Fig. 2), which was used to estimate variance-at-age and for the construction of the PM and the age structure, as described above.

M-at-Length

The algorithm used to estimate M-at-length provided values for those ages and months where fishing was closed (Table 1), where stock declination is only from natural causes. In general, M-at-age declines with age, from an average of $M_{a,t}$ = 1.48 mo^{-1} at ages between 1 and 6–7 mo, to $M_{a,t}$ = 1–15 mo^{-1} for clams around 20–24 mo old (Fig. 3a). A time variation was also observed that suggested a seasonal behavior (Fig. 3b) with higher values after mid-year. $M_{a,t}$ estimates for exploited periods were obtained interpolating values from tendency over time.

Catchability-at-Length

Catchability patterns with length have a similar shape, but a different magnitude between the two catch periods (Fig. 4), with

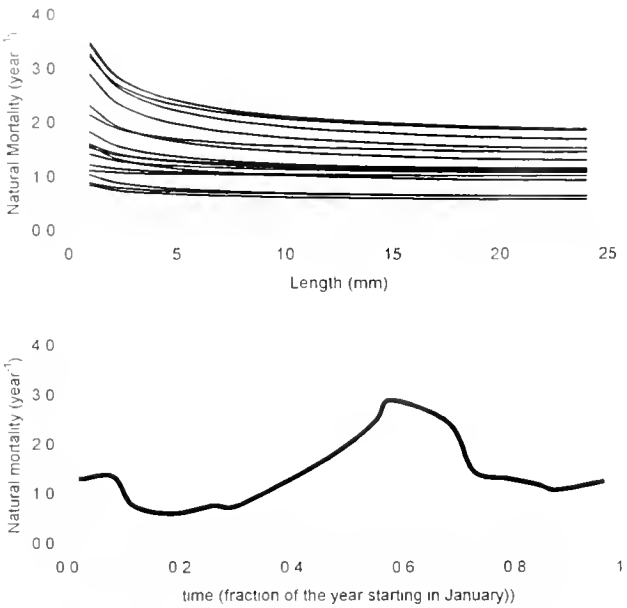

Figure 3. Natural mortality as a function of length (top) and time (bottom) for the venus clam *C. californiensis* from Ensenada de La Paz, Mexico.

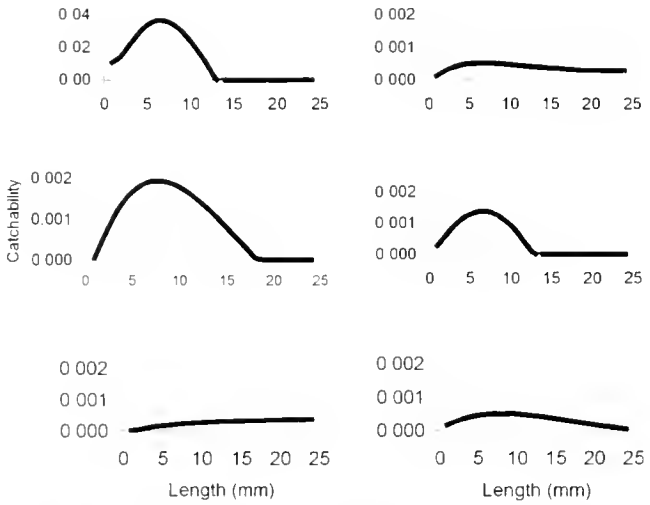

Figure 4. Catchability-at-length patterns estimated for the two fishing periods for the venus clam *C. californiensis* in Ensenada de La Paz, Mexico. Note that catchability scale for all plots is equal with exception of February (top left) where catchability is higher by one order of magnitude.

higher values for clams aged 7–8 mo. In general, catchability-at-length values were lower during September and October where relatively small values were found for clams between 4 and 12 mo, and ranging from q = 0.0003 to q = 0.00137. Higher catchability values were found during the first fishing period of the year, particularly in February where catchability varied between 0.008 to 0.036 for clams between 2 and 12 mo. Catchability decrease later during March and early April in one order of magnitude (Table 2). The main feature of catchability-at-length patterns is that catchability values for the venus clam are considerably higher for adults just before spawning (García-Domínguez & Levy-Pérez 1995).

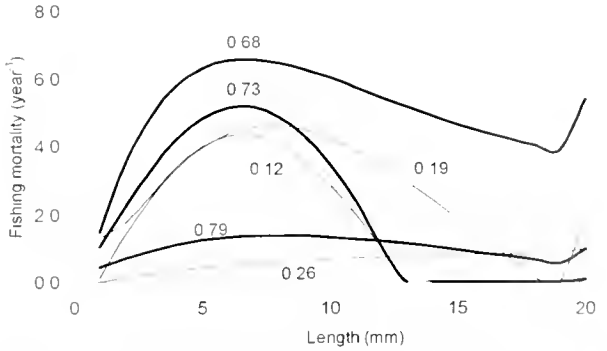

Figure 5. Fishing mortality-at-length patterns estimated for the venus clam *C. californiensis* in Ensenada de La Paz. Thin lines correspond to the period of February to early April, while bold lines are for September and October.

Fishing Mortality and Stock Size

Fishing mortality-at-age, F_a, shows a similar pattern as catchability, with higher values for clams age 6–8 months (Fig. 5), during September ($F_2 = 6.51$ mo^{-1}) and October ($F_2 = 5.04$ mo^{-1}; Table 2). García-Domínguez and Levy-Pérez (1995) reported a reproductive period from April to December with a peak from August to November. These high values of fishing mortality impact spawning stock during the peak of the reproductive season.

Even though there are two spawning seasons, stock size estimation (Table 3) indicates that dynamics are strongly governed by one strong cohort that is recruited during September and October: remaining more time in the stock than the early Spring cohort. Stock size was over 60 million clams per year, whereas catch amounted to approximately 5 million clams. Average annual harvest rate ($HR = \frac{C}{N}$) was 14%, but in September it reached a value of 0.8%. The average exploitation rate, $\frac{F}{Z}$, varied from 0.45 to 0.47 between fishing periods, but with $\frac{F}{Z} = 0.72$ in September. The average proportion of the stock under exploitation, $(\frac{F}{Z})(1 - e^{-Z})$, was 0.43, but in September it reached 0.72.

DISCUSSION

Most clam stocks are highly vulnerable to fishing and to habitat degradation. Many stocks are located in shallow waters, and species generally are associated with specific habitats. Exploitation of these stocks require special attention by managers, users, and scientists if sustainable yields are expected.

For growth estimates, length-based methods have been used for bivalves with success as shown by Vakily (1990) and Defeo et al. (1992). *C. californiensis* is a relatively short-lived species, with a lifespan of about 3 to 4 y.

M, as estimated here, indicates a decreasing pattern with age, as occurred with other clam stocks (McLachlan et al. 1996). For the clam, this behavior is expected because of density-dependent effects such as space competition during settlement and food competition once individuals have settled. M of adults decreased slowly because they have some advantages over small individuals for space and feeding. McLachlan et al. (1996) analyzed 15 clam fisheries around the world and suggested that the unharvested fraction of exploited sandy-beach stocks may be directly related to the amount of fishing because of sediment disturbance and incidental damage during the collection. For the venus clam, higher values of fishing mortality were present during September, coinciding with high values of M, as expressed by the seasonal pattern. In this case, however, higher values for M also coincide with the peak of the spawning period.

Catchability shows a large variation with size and time, representing a large variation in vulnerability to fishing. Results suggest higher catchability values are present during the prereproductive and reproductive seasons. This is of importance because great vulnerability to fishing can negatively impact the reproductive success and, together with M, it could be a potential cause for a collapsing stock. Fishing mortality reflects catchability variations, with higher values for young adults than for older clams. McLachlan et al. (1996) suggests M be directly related to stock density. For the venus clam, this is not clear, but instead, M appears to be related to spawning and the recruitment process.

Stock size estimates and the dynamics described in previous paragraphs suggest there is a dominant cohort during the year, and the population dynamics, fishing success, and yields will depend upon the size and survival of such cohort. The first aspect about stock size is that even though *C. californiensis* has a longevity of 3 to 4 y, dominant cohort practically disappears after 1 y. Survival after 1 y resulted in a poor number of individuals (less than 1%). This condition of the stock suggests that current exploitation is

TABLE 3.

done on young and prereproductive clams and it is probably not the best choice to sustain the fishery. These facts also contribute to make the venus clam an extremely fragile stock in those cases when the fishery is developed under an open access scheme or a poorly controlled exploitation, as commonly occurs with many artisanal fisheries.

These types of problems have been experienced by other clam species. Gallucci (1982) studied the fishery of *Spisula solidissima*, where the rate of loss of biomass was greater than the stock growth rate. Sasaki (1993) evaluated the state of exploitation for the *S. sachalinensis* fishery and showed that stock abundance varied strongly during the year, making this an unstable fishery. Defeo (1989) reported a depleted open-access fishery of *Mesodesma mactroides* in Uruguay that was temporally closed and reopened under a controlled management scheme after it recovered. Tarr (1994) also reported a declining fishery on the white sand mussel *Donax serra* in southern Africa, where even though several measures to control open access were attempted since 1968, all licenses were finally revoked. In Weave Bay, New Zealand, McLachlan et al. (1996) also reported a depleted stock for the toheroa clam *Paphies ventricosa*, which has not recovered despite efforts made over 20 y.

Experience with several beach clams exploited in the intertidal areas shows they are highly vulnerable to harvest because of the low costs involved in their exploitation. Additionally, loss of habitat because of human activities increases mortality. All of these aspects must be considered by managers in order to sustain fisheries. For *C. californiensis*, we also showed that highest mortality (both fishing and natural) occurred during reproduction and spawning seasons. This is an important impact on the stock, particularly under high fishing pressure in an open-access fishery.

Previous experience with clams in Bahia de La Paz and adjacent regions indicate that the lack of knowledge of population dynamics as described here was a large contributor to the decline of clam stocks. This report attempts to advise fishery managers about the relevant aspects of the population biology of the venus clam to maintain biomass and, if possible, current yields. Our advice is that this type of analysis must be made for the most recent years as a basis to simulate experiments resulting in management scenarios.

MODELING GROWTH OF THE NORTHERN QUAHOG, *MERCENARIA MERCENARIA*

CRAIG L. APPLEYARD AND JOSEPH T. DEALTERIS

Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, Kingston, Rhode Island 02881

ABSTRACT Growth of the northern quahog, *Mercenaria mercenaria* (Linné), was deterministically modeled over the life span of the bivalve as well as during its first growing season (nursery stage) in Rhode Island waters. Specifically, the von Bertalanffy growth equation was used to predict increases in shell length (millimeters), weight (grams), and the relative growth rate (% increase in weight or volume per day) at various instantaneous annual growth coefficients (K). The relative growth rate (RGR) was also determined by averaging over different time intervals including 1, 4, 7, 14, and 28 days and annually. The age at which the maximum shell length and weight was reached varied with K. A higher K (0.30) resulted in more rapid initial growth and an earlier asymptote, while a lower K (0.20 and 0.10) resulted in slower initial growth and a later asymptote. RGR averaged over an annual time interval (annual RGR) decreased rapidly as the northern quahog aged, approaching 0.5% increase/day after age 2. The annual RGR's at different K values were similar, indicating that RGR was relatively insensitive to changes in K. During the first growing season (210 days in the northeast), the increase in shell length predicted by the von Bertalanffy equation was linear with a slope determined by K, that is, a higher K resulted in a greater slope. RGR, however, varied greatly during the first growing season, decreasing from 11% increase/day at 90 days after spawning to 2% increase/day at 210 days after spawning. The RGRs at different K values were also insensitive to changes in K. There were no detectable differences between RGR determinations at a K of 0.10, 0.20, and 0.30 with varying time averaging intervals (T); however, the value of RGR at a specific time varied with the time interval used to calculate RGR. The a and b coefficients estimated for the weight-length relationship from the adult and nursery stage northern quahogs differed from each other, and published measures from Narragansett Bay northern quahogs. This suggests that researchers should use data collected from northern quahogs in a size range similar to that being modeled when estimating biomass from length and abundance data. Predicted lengths and RGRs were compared to observed lengths and RGRs from a field experiment growing northern quahogs in an experimental-scale upweller (nursery stage). Our northern quahogs grew at a K of 0.25 indicating favorable conditions for growth. Early in the experiment (between 70 and 100 days after spawning), the experimental RGR differed markedly from the predicted measure; however, after 100 days post spawning the experimental RGR followed the general trend of decreasing RGR over time, but was higher than predicted.

KEY WORDS: northern quahog, *Mercenaria mercenaria*, growth modelling

INTRODUCTION

The success of a shellfish aquaculture operation depends on optimizing production, specifically, on maximizing growth and survival. Growth is defined as an increase in the size of an individual or the mean increase in the size of a population (Malouf & Bricelj 1989). Growth is usually expressed as a change in shell length, weight, or volume. The change in size (shell length, weight, or volume) per unit time is defined as the growth rate. The growth rate is usually expressed as an absolute growth rate, a relative growth rate, or an instantaneous (specific) growth rate (Ricker 1975). The absolute growth rate describes an increase in size (shell length, weight, or volume) over a specific time interval, usually a month or year. The absolute growth rate does not account for differences in the initial size of the animal. Two northern quahogs may have the same absolute growth rate, but different initial sizes; therefore, the smaller northern quahog is growing more relative to its initial size than the larger northern quahog. To incorporate the effect of initial size on growth, the relative growth rate (RGR) or specific growth rate (SGR) is commonly employed. The RGR measures the change in size of the animal relative to its initial size. The SGR estimates the growth rate (change in weight over time) and then uses a log or natural log transformation (Jobling 1994).

A number of growth models are presented in the literature to describe the size (length or weight) of a northern quahog over time. The von Bertalanffy model is the standard for marine species (King 1995) and has been successfully applied to the northern quahog (Jones et al. 1989). Traditionally, northern quahog growth studies have focused on aging northern quahogs in the natural environment based on sclerochronology or shell growth rings (Kennish & Loveland 1980, Peterson et al. 1984, Jones et al. 1989, Rice et al. 1989, Arnold et al. 1991, Slattery et al. 1991). These studies have documented the effect of environmental conditions (Ansell 1968, Jones et al. 1989), habitat (Peterson et al. 1984, Slattery et al. 1991), and fishing pressure (Rice et al. 1989) on the growth history of the animal. In aquaculture research, sclerochronological measurements are not required for documenting growth because the age is based on time from spawning or settlement.

Growth of the northern quahog varies both temporally and spatially. Ansell (1968) documented growth of the northern quahog over its natural geographic range. Jones et al. (1989) compared Ansell's data to their own and found that northern quahogs from Narragansett Bay grew exceptionally fast during the first 2 years of life. They also reported that growth varied widely throughout the bay. They found that the von Bertalanffy estimates of the maximum shell length (L_∞) varied from 67 to 100 mm, the growth coefficient (K) varied from 0.16 to 0.30, and the time at zero length (t_0) varied from −0.05 to −0.81 years. *Mercenaria mercenaria* have been known to live as long as 40 years, although only 10% of the northern quahogs from Narragansett Bay live longer than 30 years (Jones et al. 1989). Rice et al. (1989) also documented differences in growth throughout the bay. Northern quahogs sampled from Greenwich cove exhibited an L_∞ of 87 mm and a K of 0.09, while northern quahogs from the West Passage exhibited an L_∞ of 111 mm and a K of 0.10. There are a variety of factors that could account for these differences including fishing pressure (density), environmental conditions (temperature, salinity, oxygen, and food availability), sediment type, food concentration and quality, nutrient loading, and current speed.

The diversity of growth estimates used in shellfish aquaculture

research is daunting. Malinowski (1988) described northern quahog growth as an increase in shell length (mm) over the number of days from spawning, an increase in microns per day, as well as a percent weekly increase in packed volume. Manzi et al. (1984) defined northern quahog growth in terms of increases in shell length and settled volume (biomass). Since the time intervals varied between measurements, both authors converted biomass increases into an equivalent monthly relative growth rate. Similarly, a number of studies have transformed biomass increases into daily, weekly, and monthly growth rates (Manzi et al. 1986, Malinowski & Siddall 1989, Hadley et al. 1999). Although the majority of researchers have utilized RGR to quantify northern quahog growth, Rheault and Rice (1996) successfully applied SGR to a shellfish experiment, characterizing oyster and scallop growth rates to varying degrees of food limitation.

The variability present among the above experiments makes it extremely difficult to compare growth rates between studies, because growth is being expressed during different time periods and over varying sizes. Furthermore, investigators have failed to predict or model growth under optimal conditions. More importantly, without an estimate or expectation of growth, researchers lack a baseline for comparison. In other words, observed differences in growth due to experimental treatments could be confounded by differences in the predictable growth of the animal depending on the measure used.

Thus, the purpose of this paper is to:

1. present a set of expectations for northern quahog growth over both a life time and the first season of growth based on measures of shell length, weight, and volume;
2. describe the sensitivity of RGR to changes in the growth coefficient (K) and the time averaging period over which RGR is measured; and
3. to finally compare the theoretical growth models to observations from the field and from a nursery upweller.

MATERIALS AND METHODS

The von Bertalanffy growth model was used to characterize growth of the northern quahog in the coastal waters of Rhode Island. The von Bertalanffy equation in terms of shell length is:

$$L_t = L_\infty[1 - e^{-K(t-t_o)}]$$

where L_t is the shell length at age t, L_∞ is the maximum shell length attained by the animal, K is the instantaneous annual growth coefficient, t is the age in years, and t_o is the theoretical age (years) at zero length (King 1995). Length in centimeters at time t (L_t) was converted to weight in grams at time t (W_t) by using:

$$W_t = aL_t^b$$

where a is a unit conversion factor and b is the volumetric expansion factor. The growth rate was defined as the daily relative growth rate (RGR) and as the specific growth rate (SGR). RGR was calculated as:

$$\text{RGR} = \left(\frac{W_{final} - W_{initial}}{W_{initial}}\right)(T^{-1})$$

where W_{final} is the final weight (g) and $W_{initial}$ is the initial weight (g) and T (days) is the intervening time period (Ricker 1975). The RGR is expressed as a % increase per day. The SGR was calculated as:

$$SGR = \left(\frac{LN(W_{final}) - LN(W_{initial})}{T}\right)(100)$$

where LN is the natural log, W_{final} is the final weight (g), $W_{initial}$ is the initial weight (g), and T (days) is the intervening time period. The SGR is also expressed as a % increase per day.

Growth Over the Lifetime

The increase in the length and weight of the northern quahog was characterized over the course of the bivalve's lifetime at instantaneous annual growth coefficients (K) of 0.10, 0.20, and 0.30. These growth coefficients were selected to encompass the range observed in Narragansett Bay. The maximum age (lifespan) of the northern quahog was assumed to be 40 years (Jones et al. 1989) and t_o was assumed to be +0.10 years or 36 days. A value of +0.10 was chosen because the time from spawning to settlement can take anywhere from three to five weeks depending on water temperature (Rice 1992). The L_∞ for the von Bertalanffy and the a and b weight coefficients for the length-weight relationship were based on samples collected in Narragansett Bay and are summarized in Table 1 (Jones et al. 1989, Rice et al. 1989). The daily RGR and SGR averaged on an annual basis were calculated over the life span of the quahog.

Growth During the First Growing Season

To document growth of the northern quahog during the nursery stage (2 to 14 mm) shell length, weight, and RGR were modeled during the first growing season. In Rhode Island waters, the growing season is approximately seven months (210 days) and lasts from mid April to mid November (Ansell 1968). The model was initiated at the time of spawning and t_o and L_∞ values of 36 days and 14.0 cm were used. The increase in shell length, weight, RGR, and SGR were modeled during the first growing season (36 to 210 days) at K values of 0.10, 0.20, and 0.30. The RGR during the first growing season was further investigated by varying the growth interval (T) between determinations. Specifically, growth intervals of 1, 4, 7, 14, and 28 days were used to calculate daily RGR.

Application of the Growth Model to Field and Experimental Data

The theoretical models for growth over the lifetime and during the nursery stage were applied to northern quahog growth data from Narragansett Bay and Point Judith Pond, Rhode Island. Weight-length data for northern quahogs in the size range of 60 to 140 mm were collected with a dredge in upper Narragansett Bay and analyzed for the a and b coefficients of the weight-length relationship. Data collected during the summer 1999 from an experimental-scale upweller in Point Judith Pond were used to define growth of the northern quahog during the first growing season.

TABLE 1.

Parameters used to model growth of the northern quahog in Rhode Island waters.

Coefficients		Samples Collected
L_∞	=	140 mm
t_o	=	0.10 years (36 days)
a	=	0.0004
b	=	2.80
K	=	0.1, 0.2, and 0.3

Specifically, the growth coefficient (K) was determined by non-linear regression methods (DeAlteris & Skrobe 2000); the time at length zero (t_o) was determined from a linear regression of length versus time after spawning; and the length-weight parameters (a and b) were calculated using linear regression of natural log (LN) transformed length and weight data.

RESULTS

Growth Over the Lifetime

The increase in shell length over the course of the northern quahog's 40-year life follows an asymptotic relationship (Fig. 1A). The shell length increases in an apparent linear pattern during the first two years of the northern quahog's life and then increases at a decreasing rate until the asymptote or maximum shell length is attained. The rate that the northern quahog reaches its maximum shell length varies substantially with varying K. The northern quahog reaches a maximum length of 140 mm in 11 years with a K of 0.30, in 17 years with a K of 0.20, and in 33 years with a K of 0.10. Unlike the growth function describing length over time, the weight (g) function resembles an apparent sigmoid-shaped relationship. The northern quahog's weight increases slowly during the first two years and reaches a maximum of 647 grams in 15, 23, and 39 years with a K of 0.30, 0.20, and 0.10, respectively (Fig. 1B). As the growth coefficient increases, the time required for the northern quahog to reach its maximum shell length and weight decreases. RGR over an annual time interval decreases from 3.3% increase/day during the first year to 0.5% increase/day during the juvenile years (age 1–2 years) and becomes negligible during the adult years (age 2+) (Fig. 2A). Although the same general trend was apparent for the SGR averaged over an annual time interval, the SGR during the juvenile years was about half the value of the RGR (Fig. 2B).

Growth During the First Growing Season

The increase in shell length during the first seven-month (210 day) growing season was linear, as would be expected from the von Bertalanffy growth curve (Fig. 3A). The maximum shell length reached during the first growing season varied considerably with K. The northern quahogs reached a shell length of 27 mm with a K of 0.30, a shell length of 18 mm with a K of 0.20, and a shell length of 9 mm with a K of 0.10. The increase in weight during the first growing season was exponential with a considerable lag during the first 40 days. Weights of 6.20, 2.20, and 0.30

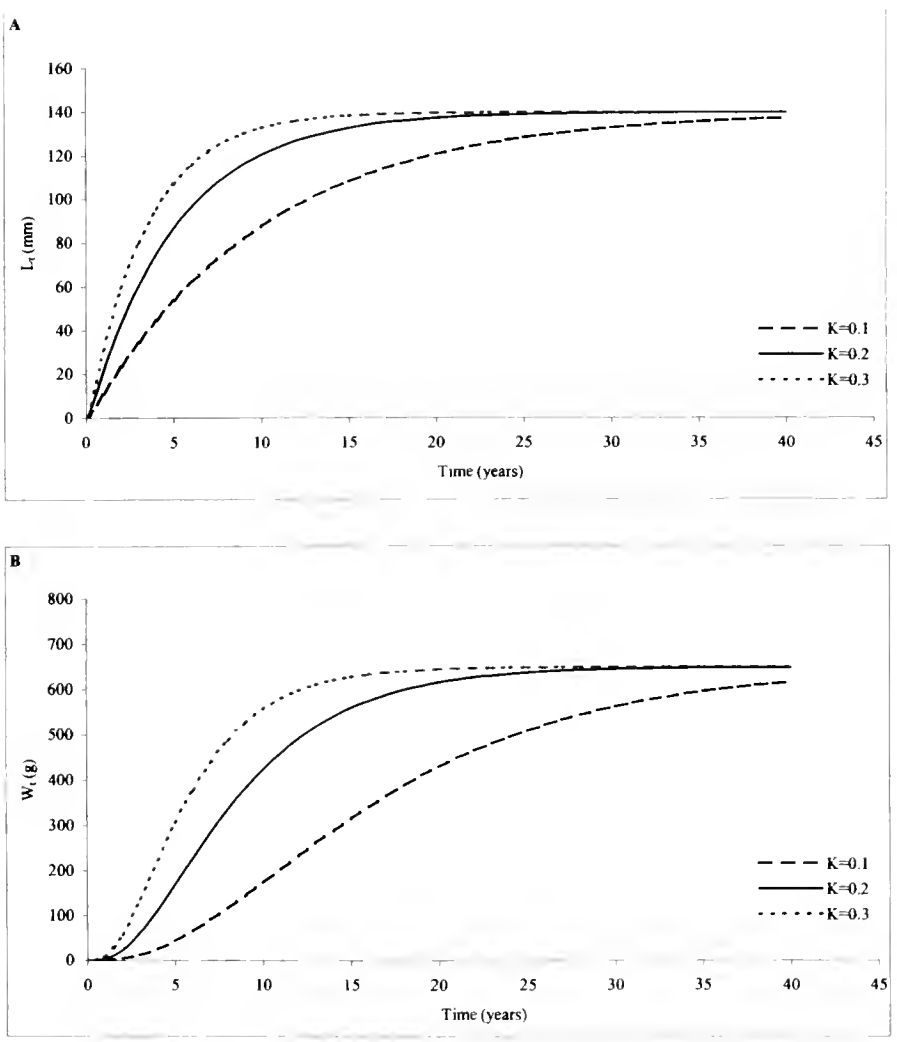

Figure 1. Length (A) and weight (B) at time for K values of 0.10, 0.20, and 0.30 over the life span of the northern quahog in Rhode Island waters.

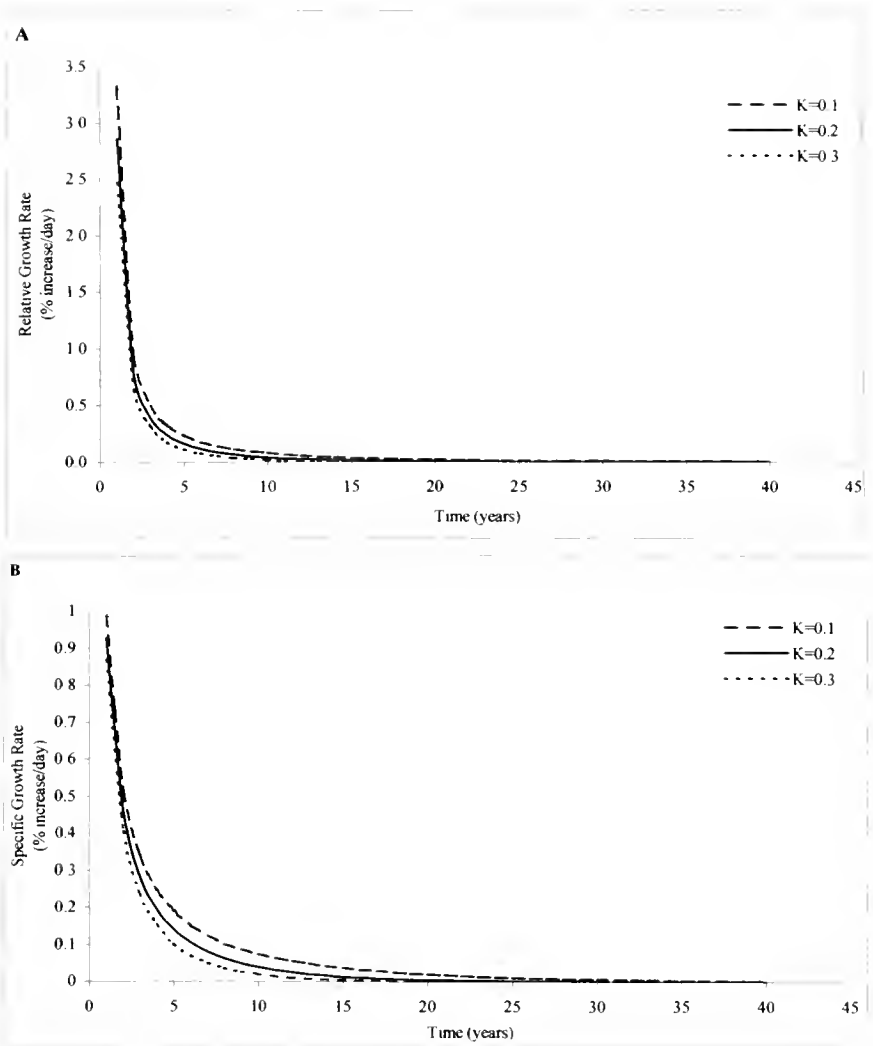

Figure 2. Daily relative growth rate (RGR) (A) and specific growth rate (SGR) (B) averaged on an annual basis at *K* values of 0.10, 0.20, and 0.30.

g were reached during the first growing season with *K* values of 0.3, 0.2, and 0.1, respectively (Fig. 3B).

The differences in final shell length and weight observed at *K* values of 0.10, 0.20, and 0.30 were not apparent when growth was converted to a RGR (Fig. 4A). Although there was a considerable change in the RGR during the first growing season, the northern quahogs displayed similar RGRs at varying *K* values. In particular, at 90 days after spawning, the northern quahogs grew at a rate of 11% increase/day, while at 150 days after spawning they grew at 3% increase/day. The RGR was high early in the northern quahogs first growing season, but decreased substantially and leveled off after 180 days post spawning. The SGR during the first growing season followed a similar pattern to the RGR (Fig. 4B).

The RGR was also determined using a variety of growth intervals. There were no detectable differences between RGR determinations at *K*s of 0.10, 0.20, and 0.30 with varying time intervals (Fig. 4A, Fig. 4B, Fig. 5A, Fig. 5B, Fig. 5C, and Fig. 5D); however, the value of RGR at a specific time varied with the time interval used to calculate RGR (Fig. 6). At 90 days after spawning, the northern quahogs grew at 26% increase/day based on a 28-day growth interval, at 15% increase/day based on a 14-day growth interval, at 13% increase/day based on a 7-day growth interval, at 11% increase/day based on a 4-day growth interval, and at 10% increase/day based on a 1-day growth interval. In other words, the larger the growth interval that RGR was averaged over, the larger the RGR. This relationship becomes less obvious when the northern quahogs reach 120 days after spawning and disappears after the first growing season (Fig. 6, Fig. 2A, and Fig. 2B).

Application of the Growth Model to Field and Experimental Data

For adult northern quahogs collected in upper Narragansett Bay, the linear regression of the LN of weight (g) versus the LN of length (cm) resulted in an R^2 of 0.94 (Fig. 7A). From this relationship, the *a* and *b* coefficients of the weight-length relationship were determined to be 0.00023 and 3.15, respectively.

For the nursery stage, the northern quahogs were spawned in 1999 April 8, at Bluepoints Company, Inc., West Sayville, New York. The linear regression of shell length versus the number of days after spawning was significant ($F(1, 6) = 132.87$, $p < 0.05$) with an R^2 of 0.96 (Fig. 8). From this relationship, t_o was estimated as 63 days after spawning. The linear regression of the LN of weight (g) versus the LN of length (cm) resulted in an R^2 of 0.99 (Fig. 7B). The *a* and *b* coefficients of the weight-length relationship were determined to be 0.00027 and 2.81, respectively.

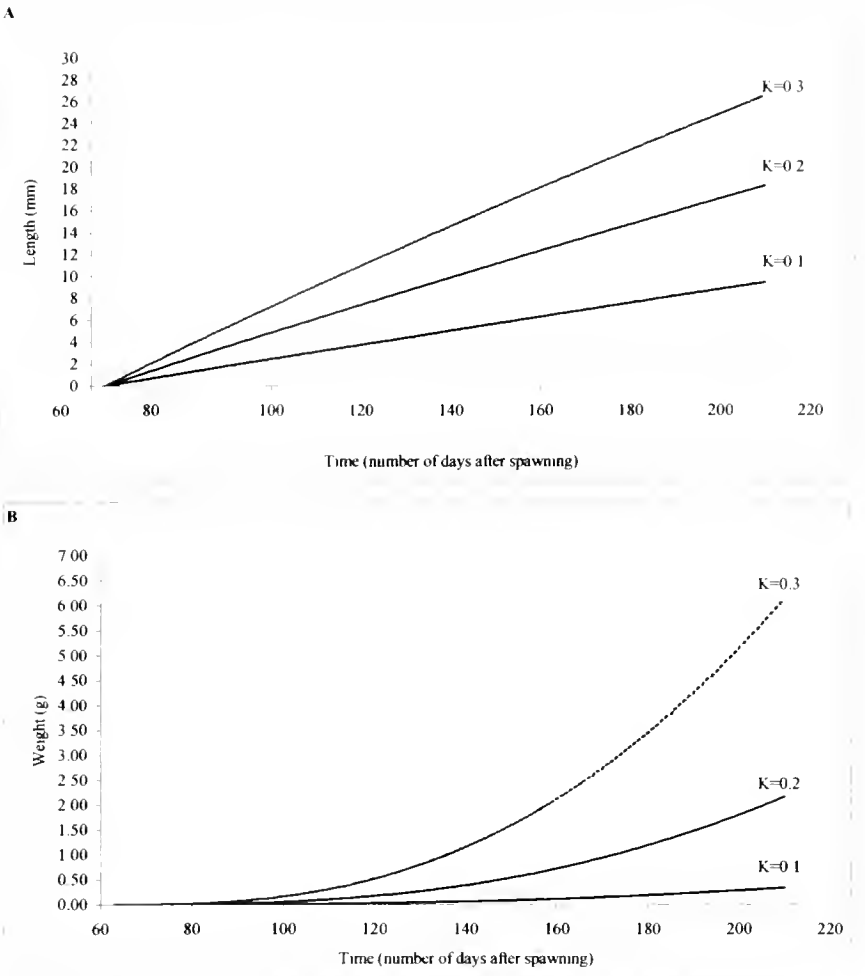

Figure 3. Length (A) and weight (B) at time for K values of 0.10, 0.20, and 0.30 during the northern quahogs first growing season.

A non-linear regression method estimated K to be 0.25 for the nursery stage growth experiment completed during the summer 1999 (Appleyard 2000) (Fig. 9). The predicted RGR was compared to the observed RGR based on a 4-day growth interval (Fig. 10). The experimental RGR varies considerably from the predicted RGR during the first 25 days of the experiment; the northern quahogs grew slower than expected. At approximately 100 days after spawning, the experimental RGR intersects the predicted curve; thereafter, the northern quahogs grew faster than expected, but tended to follow the general trend of decreasing RGR over time.

DISCUSSION

Growth Over the Lifetime

The results of this growth modeling exercise indicate that the growth rate of the northern quahog over its life span changes considerably (Fig. 1A and Fig. 1B) as a function of K. In particular, first year growth of the northern quahog is apparently linear for length and exponential for weight and both reach an asymptote as the animal ages. The age that growth reaches an asymptote depends on the particular growth coefficient (K) used. A higher K results in rapid growth and an earlier asymptote in the animal's maximum shell length and weight, while a lower K results in slower growth and a later asymptote; therefore, K is a useful indicator of environmental suitability for growth. Ansell (1968) reported the growth rates of adult northern quahogs throughout its geographical range based on annual growth rings. Within an acceptable temperature range, Ansell concluded that growth was determined by a variety of factors. Although the author successfully documented growth throughout the northern quahog's geographical range, he was unable to quantify why the northern quahogs were growing differently. A more useful measure would be the instantaneous annual growth coefficient (K). K incorporates the gamut of environmental conditions into one measure. Researchers could use K estimates to determine the health of the animal in a particular area and aquaculturists could utilize K estimates to determine the most suitable area for culture.

RGR averaged over an annual time interval decreases rapidly as the northern quahog ages, approaching 0% increase/day after age 2. RGR was relatively insensitive to changes in K. This has serious implications for experiments hoping to quantify differences in growth between treatments. Manzi et al. (1984) investigated northern quahogs in an experimental-scale upflow nursery system. The experimenters varied density to attain a range of chlorophyll-a effective flow rates and compared the growth, as expressed as RGR, between treatments. Although the investigators found qualitative differences in growth between treatments they

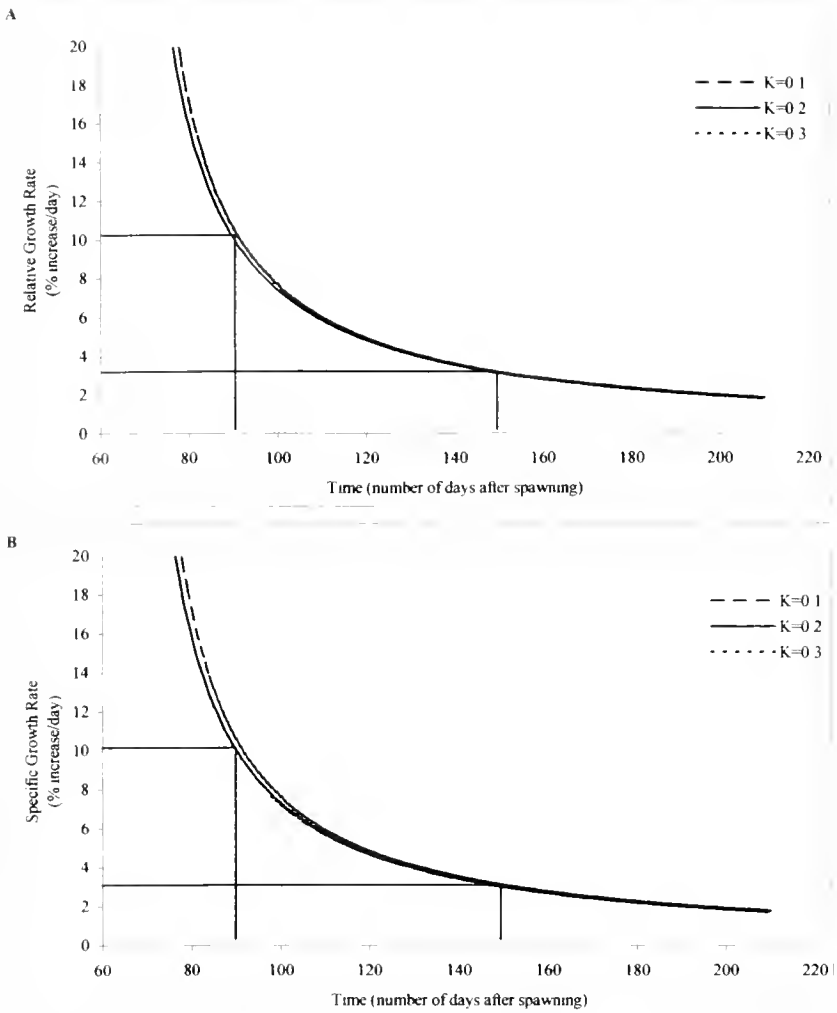

Figure 4. The relative growth rate (RGR) (A) and specific growth rate (SGR) (B) expressed as % increase/day at *K* values of 0.10, 0.20, and 0.30 during the northern quahogs first growing season in Rhode Island waters (calculated over a 1-day time interval).

did not find quantitative differences. Based on this modeling exercise, the authors would have been hard pressed to elucidate differences in growth between treatments based on RGR. A better measure to quantify differences between treatments would have been a change in length or change in weight.

SGR closely followed the patterns observed for RGR; however, because of the LN transformation, SGR during the juvenile years was about half the RGR. The LN transformation essentially compresses the growth scale and reduces the growth rate during the first two years. Comparisons between RGR and SGR are only appropriate for adult northern quahogs and should be avoided for juvenile animals. For example, Rheault and Rice (1996) measured SGR for oysters and scallops with an initial shell height of 45 and 43 mm, respectively. Their experiment monitored SGR during a six-week experiment. Since these bivalves are almost past the juvenile stage, SGR can be compared to RGR. To ensure an accurate comparison between this study and other similar experiments, SGR can be easily converted to RGR.

Growth During the First Growing Season

To predict growth during the nursery stage, growth of the northern quahog was investigated during the first growing season (210 days in Rhode Island). The increase in shell length and weight was linear. The final shell length and weight reached during the first growing season varied considerably with *K*; however, the RGR at different *K* values was almost identical. Again, the measure of RGR was relatively insensitive to changes in *K*. The RGR did vary during the first growing season. The RGR was extremely high early in the growing season (at 90 days after spawning the predicted RGR was 11% increase/day), but then decreased substantially and leveled off (at 150 days after spawning the predicted RGR was less than 4% increase/day).

The RGR was further investigated by altering the time period between RGR determinations. There were no observable differences between RGR at *K*s of 0.10, 0.20, and 0.30 with varying time intervals of 1, 4, 7, 14, and 28 days (Fig. 4, Fig. 5A, Fig. 5B, Fig. 5C, and Fig. 5D). In other words, RGR does not detect differences in the instantaneous growth rate (*K*). The value of RGR at a specific time varied with the time interval used to calculate RGR. Specifically, at 90 days after spawning there was a considerable difference between the RGR calculated over a 28-day interval and the RGR calculated over a 4-day interval (Fig. 6). Investigators should keep in mind that when comparing the results of growth experiments with different time intervals, observed differences in

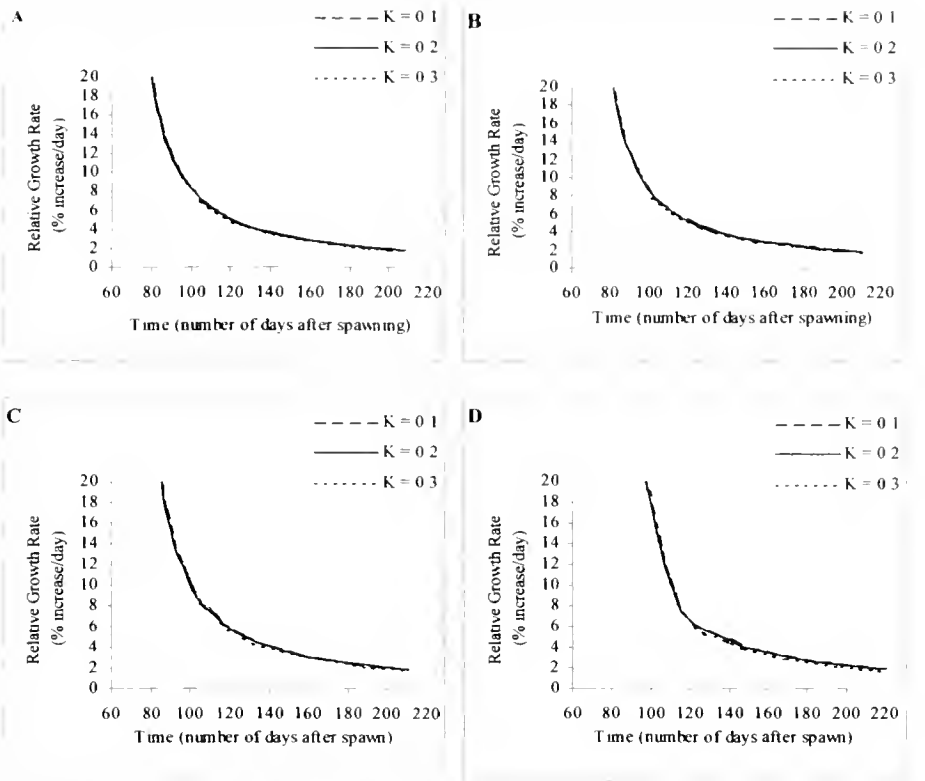

Figure 5. The relative growth rate (RGR) expressed as % increase/day over time at varying *K* calculated over: 4-day time interval (A); 7-day time interval (B); 14-day time interval (C); and, 28-day-time interval (D).

RGR may be due to differences in the time interval, not due to actual differences in growth.

Application of the Growth Model to Experimental Data

The *a* and *b* coefficients estimated for the weight-length relationship from the adults and nursery stage northern quahogs were different from each other and from other values published for Narragansett Bay northern quahogs. This suggests that researchers should always use data collected from locally available northern quahogs in a size range similar to that being modeled when estimating biomass from shell length and abundance data.

The relative growth rate changes considerably during the first growing season. The growth rate depends on the size of the animal as well as the time period between measurements. Growth studies on upwellers have not taken into account these differences. In addition, the variability between growth measurements has prohibited meaningful comparisons between research studies. Manzi et al. (1984) converted their biomass increase to a monthly percent increase because the time interval between volume determinations varied. The investigators failed to take into account changes in the growth rate at different time intervals. A study completed by Hadley et al. (1999) found a relationship between the daily growth rate (DGR) and flow ratio at varying northern quahog shell lengths. In particular, the authors found that the DGR increased as the size of the animal decreased. Based on the results of this

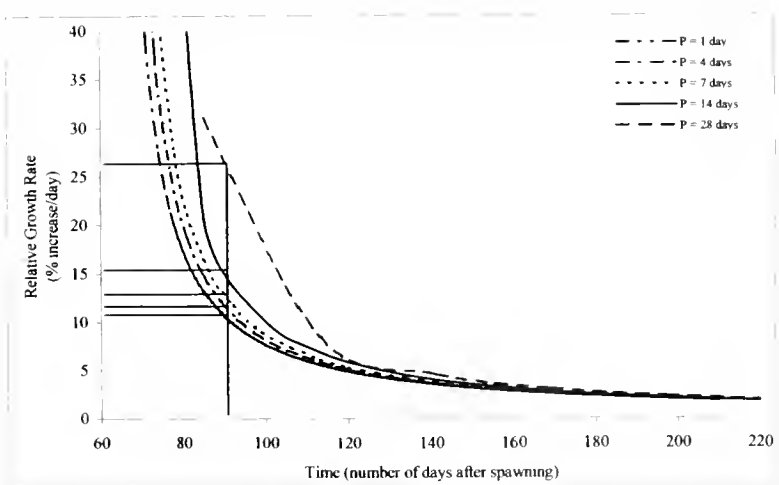

Figure 6. The relative growth rate (RGR) expressed as % increase/day over time at varying time intervals for a single *K* value of 0.20.

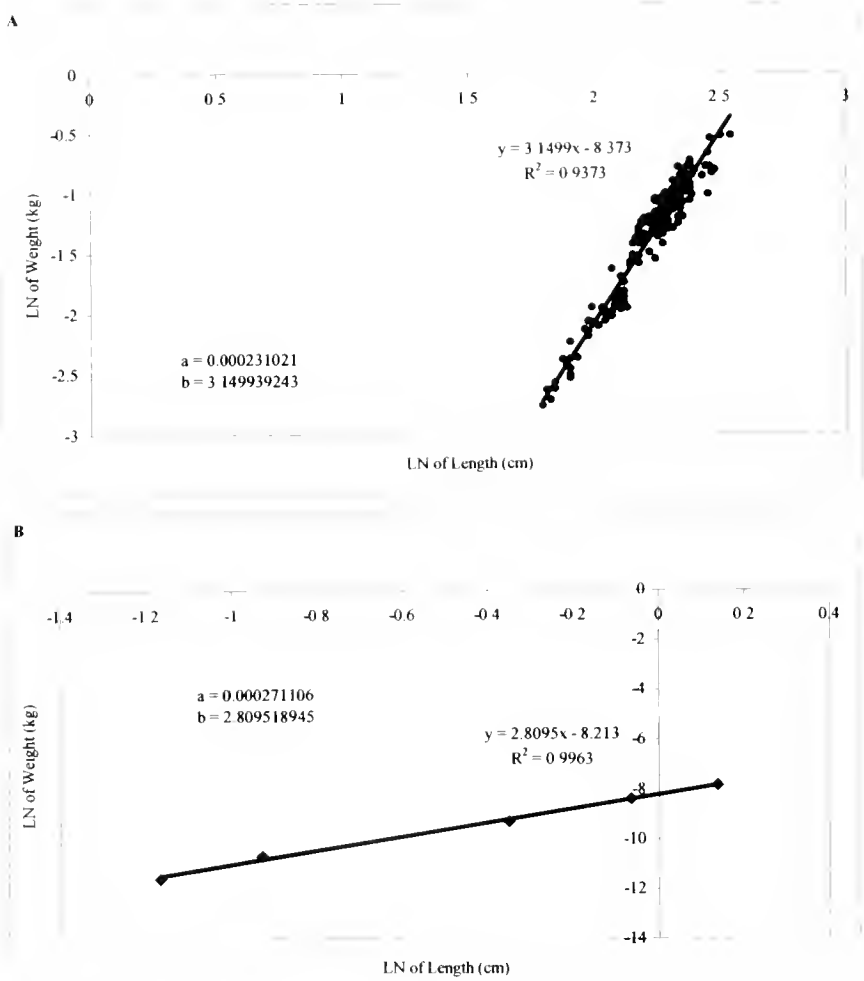

Figure 7. Linear regression of the natural log (LN) of weight (kg) and LN of length (cm) of adult northern quahogs sampled from Narragansett Bay (A) and of juvenile northern quahogs sample from an experiment in Point Judith Pond (B).

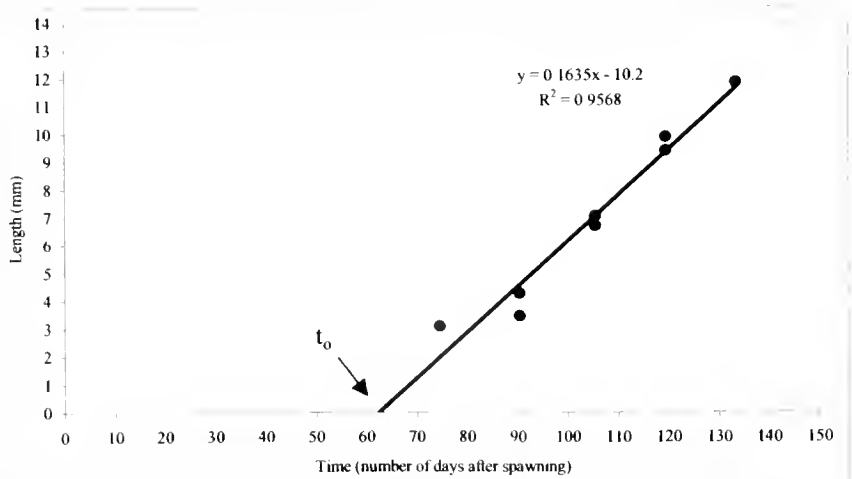

Figure 8. Linear regression of shell length (mm) with time (number of days after spawning) used to estimate t_o from juvenile northern quahogs sampled during the summer 1999.

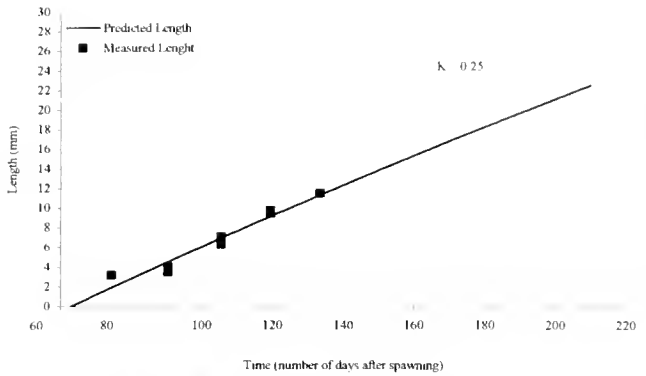

Figure 9. Observed shell length during the summer 1999 along with the predicted shell length at a *K* of 0.25 during the northern quahog's first growing season in Rhode Island waters.

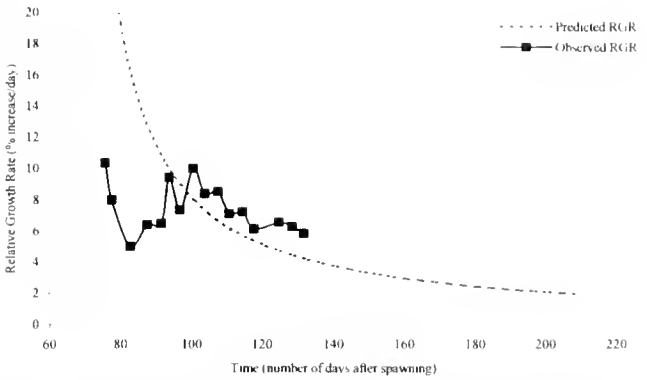

Figure 10. The predicted relative growth rate (RGR) versus the observed relative growth rate (RGR) during the first growing season on the northern quahog (calculated over a 4-day growth interval).

modeling exercise, the RGR is expected to increase with decreasing size. The relationship developed by the authors correlates well with predicted growth in the natural environment.

During the upweller experiment completed in the summer 1999 (Appleyard 2000, DeAlteris 2000), the northern quahogs grew with a *K* of 0.25, indicating average conditions for growth. A *K* of 0.25 approaches the maximum *K* observed by Jones et al. (1989) in Narragansett Bay, but in a culture situation, higher *K* values should be expected.

A predicted RGR was compared to the observed RGR during the aforementioned study. Early in the experiment, between 70 and 100 days after spawning, the experimental RGR differs markedly from the predicted RGR; however, 100 days after spawning the experimental RGR was higher than expected and followed the general trend of decreasing RGR over time. To incorporate the influence of anticipated growth on the experiment, the residuals between the predicted and experimental RGR were determined. The residuals were then compared to key environmental conditions to elucidate their effect on growth. Although there were no clear conclusions, this exercise was important in accounting for anticipated changes in growth over the first year of the northern quahog's life.

REPRODUCTIVE STRATEGIES IN TROPICAL BIVALVES (*PTERIA COLYMBUS*, *PINCTADA IMBRICATA* AND *PINNA CARNEA*): TEMPORAL COUPLING OF GONAD PRODUCTION AND SPAT ABUNDANCE RELATED TO ENVIRONMENTAL VARIABILITY

H.-JÖRG URBAN

Alfred Wegener Institute for Polar and Marine Research, Section for Comparative Ecosystem Research, Postfach 12 01 61, 27515 Bremerhaven, Germany

ABSTRACT The effects of environmental variability (El Niño 1997/1998) on three Caribbean bivalves (*Pteria colymbus*, *Pinctada imbricata* and *Pinna carnea*) were studied based on time series (1994 to 1998) of temperature, salinity, particulate organic matter (POM), larval and spat abundance. Monthly condition and gonad production cycles over a 12 months period are used to investigate whether these processes are coupled with recruitment.

The findings clearly show that El Niño 1997/1998 increased POM, decreased salinity and had little effect on temperature. In contrary to the Pacific, these changes in the study area were not caused directly, but by increased precipitation and no significant effects on larval or spat abundance were observed. The findings show similarities for the two closely related pearl oysters (*Pteria colymbus* and *Pinctada imbricata*), such as correlated larval and spat abundance cycles, and a negative correlation between temperatures and spat (whereas temperature was positively correlated with *Pinna carnea* spat). However, due to fewer spat peaks and a lower mean spat abundance, the uncoupling of gonad production and spat abundance, as well as less continuous gametogenic activity, a different reproductive strategy for *Pteria colymbus* is indicated.

KEY WORDS: bivalves, pearl oysters, fan shells, reproductive strategy, gonad production, larval abundance, spat abundance, El Niño, Caribbean

INTRODUCTION

Environmental variability can be seen in the context of latitudinal dependent environmental changes (i.e., seasonality) or interannual climate changes, (e.g., the climate anomaly El Niño). These environmental changes affect biological processes such as the reproduction and recruitment of marine species. Regarding seasonality it is generally accepted that as an adaptation to decreasing seasonality of environmental factors from polar to tropical regions (Lalli & Pearsons 1993) marine invertebrates from high latitudes have shorter spawning and recruitment periods, while at low latitudes longer and more continuous periods dominate. In the literature we find little published results on the relation between energy allocated to reproduction and temporal larval or spat variability in tropical benthic invertebrates. This might be explained by the fact that the reproductive output of animals with planktonic eggs and continuous reproduction are difficult to assess, and this reproductive strategy is likely to be very common among warm temperate and tropical benthic species (Crisp 1984).

El Niño might be regarded as an oceanographic phenomenon regionally restricted to the South American Pacific coast principally off Peru and North Chile which on statistical average occurs every three to seven years. Here, under El Niño conditions, the cold and nutrient rich upwelling system changes towards warm and nutrient-poor conditions that can lead to catastrophic consequences for the marine ecosystem (Arntz & Fahrbach 1991). Apart from effects on the marine ecosystem, impacts of El Niño on the terrestrial ecosystems of the South American continent, such as increasing rainfall in deserts and droughts in otherwise humid regions, can be observed. For example in the South American Caribbean, which is not affected directly by El Niño, different precipitation patterns lead to secondary (indirect) oceanographic changes, and thus effects upon the marine ecosystem can be assumed. Among the many reports of El Niño impacts on marine ecosystems, the results of Urban (1994) and Urban and Tarazona (1996) are most relevant to this study. They postulate that for several bivalve species, El Niño normally only affects the energy balance (such as metabolism, growth rate, gonad output), larval survival and recruitment. These two studies so far seem to be the only long-term approaches quantifying the effects of El Niño on marine benthic invertebrates of South America.

Pearl oysters (family Pteriidae) and fan shells (family Pinnidae) are of commercial importance, as reflected by the quantity of publications devoted to aquaculture and spat settlement (for pearl oysters see review in Urban 2000a). For fan shells (different *Atrina* species and *Pinna rugosa*), see studies on ecology, fishery and aquaculture by Arizpe and Félix (1986), Cendejas et al. (1985), Baqueiro and Castagna (1988), Davy and Graham (1982), Philipson (1989), Turner and Rosewater (1958). In the Caribbean waters of Colombia, the dominant pearl oysters are *Pteria colymbus* and *Pinctada imbricata* and the fan shells are represented by *Atrina serrata*, *Atrina seminuda* and *Pinna carnea*, with the latter being the most dominant. *Pteria colymbus* lives attached to octocoral communities, *Pinctada imbricata* was found to be the dominant sessile species in sea grass (*Thalassia testudinum*) communities (Urban 2000a) and *Pinna carnea* favors medium to coarse sandy substrates or mixed substrata (sand-rocks-corals). All three species are epifaunal species distributed in depths between 0.5 m to 15 m. Except for Urban 2000a and Urban 2000b on the aquaculture and population dynamics of *Pinctada imbricata*, no further information on pearl oysters and fan shells from this region was found in the reviewed literature.

The objectives of this paper are to study possible effects of oceanographic changes caused by El Niño on reproduction and recruitment of three tropical bivalve species. Furthermore, the cyclic reproductive patterns and temporal coupling of gonad production and spat variability are investigated. This includes duration of larval development under laboratory conditions and spat growth experiments. Reproductive strategies are discussed.

MATERIALS AND METHODS

Study Area

Spat and larval abundance and environmental factors, were monitored monthly between 1994 and 1998 in Chengue Bay, Tay-

rona National Nature Park (11°20′N, 74°10′W, Fig. 1a). Gametogenic activity and condition cycles were studied monthly during one year, but during different years for each species: *Pteria colymbus* (1,354 specimens) were sampled between March 1994 and February 1995 in Tayrona Park, *Pinna carnea* between April 1995 and April 1996 (1469 specimens from Tayrona Park) and *Pinctada imbricata* between March 1997 and March 1998 (782 specimens) in the "Cabo de la Vela", a Peninsula located in the Guajira province (12°10′N,72°20′W and 12°00′N, 72°10′W), approx. 300 km from the Tayrona Park (for detailed description of the Cabo de la Vela study area see Urban 2000a, Fig. 1b). Tayrona Park consists of several small bays offering a great variety of substrates (patches of sea grass, coral reefs, sandy-silty substrates and mixtures of coral and sand bordered by mangroves). Annual water temperatures vary between 26°C and 30°C with a mean salinity of 36‰ and a tidal range of less than 30 cm.

Sampling

Monthly zooplankton samples were taken between 9:00 and 11:00 a.m. with a Bongo net (○ 35 cm, mesh size 150 µm, filtering 25–30 m^3 seawater). Samples were preserved in 70% alcohol and all bivalve larvae of the genus *Pinctada*, *Pteria* or of the family Pinnidae were identified and counted. For larval identification, "morphotypes" from laboratory reared larvae, were compared with larvae obtained from zooplankton samples. Spat abundance was determined deploying collectors (="traps") that consisted of three plastic mesh "onion bags" (80 × 30 cm, mesh size 0.8 cm), protected by a propylene net-bag. Collectors were tied to a bottom long line at 5 and 10-m depths, and recovered 6 weeks later. Mean abundance collector^{-1} was determined at monthly intervals. At each sampling date bottom temperature and salinity were recorded and seston samples were taken at 3-m water depth with a pump. Seston samples were filtered using Whatman Glass Microfibre filters, which were dried for 24 hours at 70°C. Particulate organic matter (POM) was calculated after ignition of filters at 500°C for 4 hours.

Gametogenic Activity, Condition and Gonad Production

Maximum length (anterior-posterior axis) was recorded for all specimens with vernier calipers. Two sub-samples of 30–40 individuals each were selected randomly covering the entire size range. One sub-sample was used for gametogenic analysis. Every month the reproductive stage of 30 individuals was determined based on microscopic observation on fresh gonad material (smear samples) using a semi quantitative scale (Urban 2000a: indifferent, developing 1, developing 2, ripe, spent). With the second subsample the condition (body weight cycle) was determined. Soft parts were removed and dried at 70°C to constant weight to determine shell free dry weight (SFDW). Ash free dry weight (AFDW) was obtained by ignition of dried soft parts at 550°C for five hours. Parameters "a" and "b" of the monthly relationships between shell length and shell-free dry weight (Eq. 1) were estimated with non-linear regression analysis. An annual shell free dry weight (i.e., condition) cycle for a standard individual was calculated as

$$SFDW = a \cdot SL^b \quad (1)$$

where SFDW is the shell free dry weight [g] and SL the shell length [mm]. Gonad production was estimated using a new method (for details see Urban & Riascos submitted) based on monthly quantitative samples, monthly length-gonad weight relationships, pooled annual length frequency data and observation of the gametogenic activity. First the gonad region was replaced by geometric abstractions. With linear measurements of the gonad region and geometric equations corresponding to geometric bodies, the gonad volume and thus the monthly gonad weights were estimated. Assuming the gametogenic stage "ripe" corresponds to the part of the population which spawns during a particular month, the monthly spawned gonad weight for each size interval was estimated. Finally, the annual gonad production of the entire population is given by the sum of all months and length class intervals according to Eq. 2.

$$W_{gon\_ann\_pop} = \sum [W_{gon_{i,j}} \cdot P_{spawn_{pop_{i,j}}}] = \sum \left[\left(\frac{V_{gon_{i,j}}}{V_{tot_{i,j}}} \cdot W_{tot_{i,j}} \right) \cdot \left(\frac{\left(\frac{n_i}{\sum n} \cdot A \right) \cdot ripe_j}{100} \right) \right] \quad (2)$$

$W_{gon\_ann\_pop}$ annual gonad production of the population [g AFDW m^{-2} yr^{-1}]
$W_{gon\,i,j}$ gonad weight per length interval "i" during month "j" [g AFDW]
$P_{spawn_{pop_{i,j}}}$ part of the population spawning per length interval "i" during month "j"
$V_{gon\,i,j}$ gonad volume per length interval "i" during month "j" [ml]
$V_{tot\,i,j}$ total body volume per length interval "i" during month "j" [ml]
$W_{tot\,i,j}$ total body weight per length interval "i" during month "j" [g AFDW]
n_i number of specimen in length interval "i"
Σn total number of specimen of the pooled length frequency sample [yr^{-1}]
A mean abundance from quantitative samples [n m^{-2}]
$ripe_j$ part of the population with gametogenic stages "ripe" during month j [%].

Gonad production could not be estimated for *Pinna carnea* due to lack of quantitative samples.

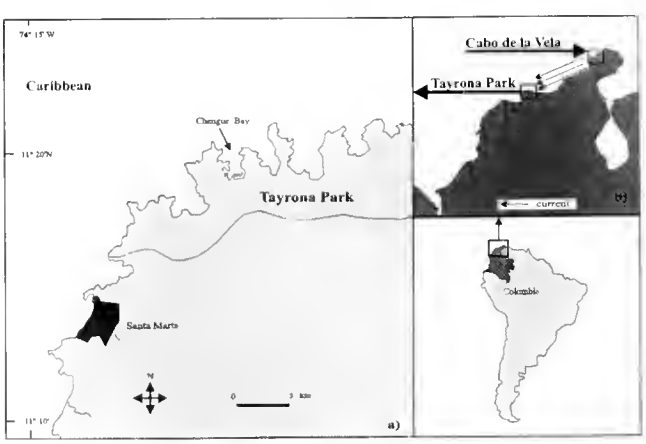

Figure 1. Study area. Tayrona Park, Caribbean of Colombia.

Larval Development and Settlement

Adults of *Pinctada imbricata* were adapted for four weeks to laboratory conditions (ultraviolet-irradiated, 45 µm filtered seawater, 23°C–25°C, 34‰, fed on a 1:1 mixture of *Chaetoceros gra-*

cilis and *Isochrysis galvana*). During a spawning trial the temperature was gradually increased every 10 minutes up to 34 C. Fertilization was initiated mixing eggs and sperm in a 1:10 ratio. Larvae (three replicates) were transferred to 500 L tanks at an initial density of 6 larvae ml^{-1} and fed on different diets of *Isochrysis galvana* and *Chaetoceros gracilis* (to day 15: 50.000 cel. ml^{-1}, after day 15: 100.000 cel. ml^{-1}). Water was changed every two days. From day 15 on, a propylene net material was placed in the tanks during larval settlement. Larval growth was studied for 37 days by microscopic measurement of the anterior-posterior length of approximately 10–15 larvae every 5 days. From day 47 to day 88 the growth rate of 50 post-larvae (initial shell length 2.9 mm ±0.675 S.D.) placed in pearl nets (three replicates) under natural conditions (Urban 2000b) was followed by measuring 10–15 individuals from each replicate every 5 days.

Analysis of Time-Series Data

In order to study possible cyclic patterns of larval and spat abundance, as well as abiotic data (temperature, salinity and organic matter), time series were analyzed with autocorrelation plots and Fourier analysis. Data were smoothed with moving averages (over four), interpolating missing data. Furthermore, time series were normalized according to "(x-mean)/standard deviation" and the positive values surpassing the mean, i.e., the positive peaks were plotted.

RESULTS

Larval and spat growth can be described by power functions yielding high determination coefficients (Fig. 2). Larvae took 17 days to grow from straight-hinged larvae to pediveliger (8 μm day^{-1}). Thereafter, during the following 11 days from pediveliger to spat it was 83 μm day^{-1}, and finally, during the last 10 days of this particular experiment, growth increased to 112 μm day^{-1}. From day 47, mean growth of spat under natural conditions was 198 μm day^{-1}.

Figure 3 shows the gametogenic activity and condition cycles, recorded during three different years (Fig. 3a), the larval and spat abundance (Fig. 3b, 3c, 3d), and the environmental factors (Fig. 3e, 3f) for the entire period (1994–1998), in order to give a general overview of the available data. Autocorrelation plots (not shown) on all time series data (i.e., data of Fig. 3b, 3c 3d, 3e, 3f), except for temperature, were highest and significant (surpassing the 95% confident interval) at Lag 1 (with rather low values between 0.484 and 0.622) or at Lag 2 (with values between −0.604 to −0.725). In

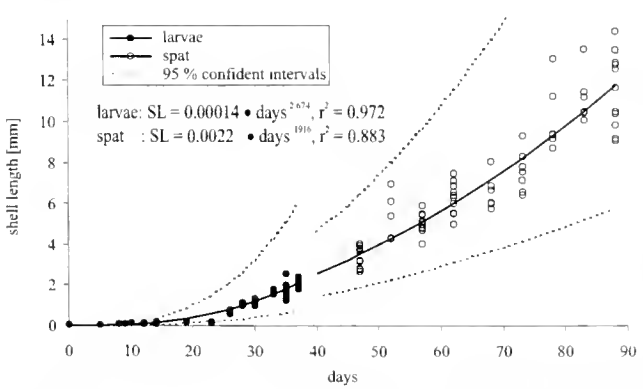

Figure 2. Larval growth under laboratory conditions and spat growth under natural conditions of *Pinctada imbricata*.

time series data we expect significant correlation at low Lag's (i.e. a particular value depends on a value one time unit earlier). However, the lack of significant correlation at higher Lag's, indicates the absence of a cyclic pattern of these variables, which was confirmed by Fourier analysis. Significant values were only obtained for temperature at Lag 1 (=0.536), Lag 6 (=0.763) and Lag 12 (=0.480), indicating a 12-month cycle, which was confirmed by Fourier analysis giving one high peak (of square magnitude) at a period of 10.7 months.

The El Niño effects on oceanographic factors show less temperature and salinity and more POM peaks from 1997 on (= beginning of El Niño, Fig. 4). This indicates a strong salinity and a slight temperature decrease as well as a strong POM increase. In order to correct the El Niño effects which mask the salinity and POM peaks, these two factors were normalized for two periods (pre-El Niño: March 1994 to December 1996, El Niño: January 1997 to August 1998). To quantify the relation between all time series, a Spearman correlation analysis was carried out (Table 1). Larval cycles could not be related conclusively to spat cycles (Fig. 5). For example in *Pteria colymbus* the first two larval peaks occurred immediately after the spat peaks. The Spearman correlation confirmed these results giving low values of <=0.2 between larval and spat cycles of the same species. However, the larval cycles of all three species seem to follow a similar pattern, given by higher correlation values (*Pteria colymbus/Pinctada imbricata* = 0.6, *Pinna carnea/Pinctada imbricata* = 0.7 and *Pteria colymbus/Pinna carnea* = 0.4). Low values were found for the correlation between any of the environmental factors and larval abundance and a negative correlation between temperature and salinity was indicated (−0.5). During the entire study period (54 months), *Pteria colymbus* exhibited only four annual short peaks between December to March of each year, whereas *Pinctada imbricata* and *Pinna carnea* had seven peaks in the same time (Fig. 5, Fig. 6).

The normalized cycles of SFDW (a), gonad production (b), spat abundance (c) and temperature as well as salinity (d) are given in Figure 7. Due to the fact that gonad production could not be estimated for *Pinna carnea* (see methods), in this case the gametogenic stage "ripe" is shown (Fig. 7b). For *Pinctada imbricata* SFDW, gonad production and spat abundance cycles agree extremely well as in all cycles 3 peaks are found in the same months (beginning, middle and end of the year, indicated by black arrows). For *Pinna carnea* SFDW and "ripe" are not well coordinated; SFDW peaks in the second half of the year and the reverse is true for the "ripe" cycle (with 2 peaks in the first half of the year), however "ripe" and spat peaks are in line. For *Pteria colymbus* SFDW and gonad production have 2 peaks in the first half of the year while the spat cycle with one peak at the end of the year does not seem to be related at all. No conclusive relationship is indicated with either of the environmental factors. In 1994 and 1995 temperature and salinity cycles peak at different times of the year, indicating a negative correlation, while in 1997, with the beginning of El Niño, this pattern seems to have changed as salinity and temperature peak at the same time.

Finally, the effects of El Niño on environmental factors and spat variability are summarized (Fig. 8). Clearly the El Niño had an effect on salinity and POM, as salinity on average decreased from 36.25‰ to 34.75‰ and POM increased from 0.25 to 0.6 mg l^{-1}. However, no conclusive results were obtained indicating that these oceanographic changes had any significant influence on spat abundance, though *Pteria colymbus* seems to typically have a lower spat abundance.

DISCUSSION

In areas with a strong seasonality, reproduction (maturation and spawning) is often found to be triggered directly by temperature (Alagarswami 1966, Urban & Campos 1994). Alternatively, many reports on temperature as an indirect trigger have been published. For example larvae abundance (*Mytilus edulis*, and *Macoma balthica* larvae from the North Sea) are correlated to algal bloom in summer that depends on temperature (Niesel & Günther 1999). In the current study under tropical conditions we would have expected that reproduction depends on salinity and food availability rather than on temperature (Barnes 1957) because compared to temperate and Polar Regions in the tropics, annual temperatures are less variable. However, this prediction could not be confirmed, on the contrary spat abundance was best correlated with temperature.

Recruitment (i.e., spat abundance) that follows after reproductive processes such as gonad production and spawning can be assumed to be temporally coupled. However, the literature gives numerous examples where reproduction and recruitment are highly variable and uncoupled. This is explained by factors such as patchy food supply for larvae (Langdon 1983), thus, causing an extension of the developmental period and a reduction of survival owing to larval food limitation (Olson & Olson 1989). Furthermore, oceanographic processes influencing larval dispersal (Strathman 1974) and—especially in tropical regions—longer continuous reproductive periods uncouple reproductive processes. This study confirmed these results in the case of larval and spat abundance: Although in several cases larval and spat abundance is in line, the general picture is that both cycles are variable following different patterns. Apart from the possible explanations stated above, this could be due to the fact that zooplankton samples were taken only monthly. Thus, peaks could easily have been missed, whereas spat abundance that was recorded from collectors left for six weeks could be assumed to be more reliable. This aspect is important because at least for *Pinna carnea* and *Pinctada imbricata*, reproduction (gametogenic activity or gonad production) correlate extremely well with spat abundance while in *Pteria colymbus* these processes seem to be uncoupled. Owing to a lack of data for *Pinna carnea*, instead of the gonad production the gametogenic stage "ripe" is given. Urban and Riascos (submitted) found the monthly gonad volume cycle and the gametogenic stage "ripe" cycle of *Pinna carnea* from Tayrona Park to be positively correlated, explaining this finding as follows: The gametogenic stage "ripe" gives the percentage of specimens with ripe gonads (shortly before spawning). Gonads are most voluminous in this development stage as egg and sperm size is large. As the method to estimate gonad production is based upon the monthly gonad volume, gametogenic stage "ripe" and gonad production are also correlated.

The apparent "direct" coupling of reproduction and recruitment in *Pinna carnea* and *Pinctada imbricata* at first appears suspicious because a time lag would have been expected, i.e., spat peaks and gonad production peaks should not be observed at the same time. Larval periods of bivalves have been the subject of numerous studies, and it is obvious that their duration depend principally on temperature and food. For example, the larval development of *Donax serra* from the productive and temperate Benguela upwelling system lasts 3–4 weeks (Birkett & Cook 1987, Donn 1987), and for the tropical *Pinctada maxima* the larval development time is 28–35 days (Rose & Baker 1994). Besides this "time problem" it has to be taken into account that gonad production of *Pinctada imbricata* was recorded for a population in Cabo de la Vela, 300 Km from Tayrona Park (where spat experiments were carried out). However, *Pinctada imbricata* spat from collectors after 6 weeks ranged from 1–4 mm shell length, which is in good agreement with larval growth experiments in which spat after 6 weeks had a mean length of 2.8 mm. Furthermore, laboratory-reared spat used for growth experiments after 6.7 weeks measured 2.9 mm (±0.675 S.D.). The question remains whether larvae could have been transported from Cabo de la Vela to Tayrona Park within this time. The Caribbean Current (Thurman 1994) flows parallel to the Colombian coast into the Gulf of Mexico with a velocity of 0.5 m s^{-1} (Tomczak & Godfrey 1994), thus spawned *Pinctada imbricata* larvae can be transported from the Cabo de la Vela to Tayrona Park within 6.9 days (Fig. 1b). According to laboratory experiments, larval development until settlement lasts 23–28 days. Assuming a similar development time for *Pinna carnea*, "collector periods" of six weeks would lead to such overlapping peaks of recruitment and reproduction as found in Figure 6, with no time lag between coupled gonad production and spat peaks being observed.

At high latitudes seasonality is principally governed by the large annual temperature variability, and at low latitudes (i.e., the tropics) with more constant temperatures, there is little seasonality. However, a clear seasonality of environmental factors other than temperature can be observed in tropical regions. In the study area a combination of precipitation and wind patterns seem to be the principal driving force. Annually, the rainy season (normally between June and November) is followed by the dry season (normally between December and May). Precipitation decreases salinity and the run off of nutrients increases POM. On the other hand a local upwelling (Blanco 1988) towards the end of the rainy season leads to a drop of mean temperature (?4°C). This explains the apparent negative correlation between temperature and salinity.

As mentioned above, El Niño increases precipitation in the semi-arid region of the Colombian Caribbean close to Venezuela. Thus, decreasing salinity, increasing POM and negligible effect on temperature during El Niño can be postulated. This is an interesting parallel comparing El Niño effects in the South American Pacific where temperature increases, and (in the pelagic regions), nutrients decrease. In the Caribbean, salinity variability owing to

POM	0.2	0.1	0.1	0.0	0.0	−0.2	0.1	0.0

El Niño most likely has little influence on the ecosystem. In the Pacific however, the reduction of nutrients during El Niño, leads to a characteristic breakdown of food chains (Glynn 1988, Enfield 1988, Arntz & Fahrbach 1991). Considering that in the Caribbean during El Niño 1997–1998 POM increased almost three fold, it could be assumed that suspension feeding secondary producers such as bivalves benefited from the increased POM pool, gaining more energy for production.

However, except for *Pinctada imbricata*, no differences in larval or spat abundance that could be attributed to El Niño-induced changes of environmental factors were observed in this study. Moreover, *Pinctada imbricata* rather showed a reduction of spat abundance during El Niño. This finding might be explained by noting that filtration rates of filter feeding bivalves are positively

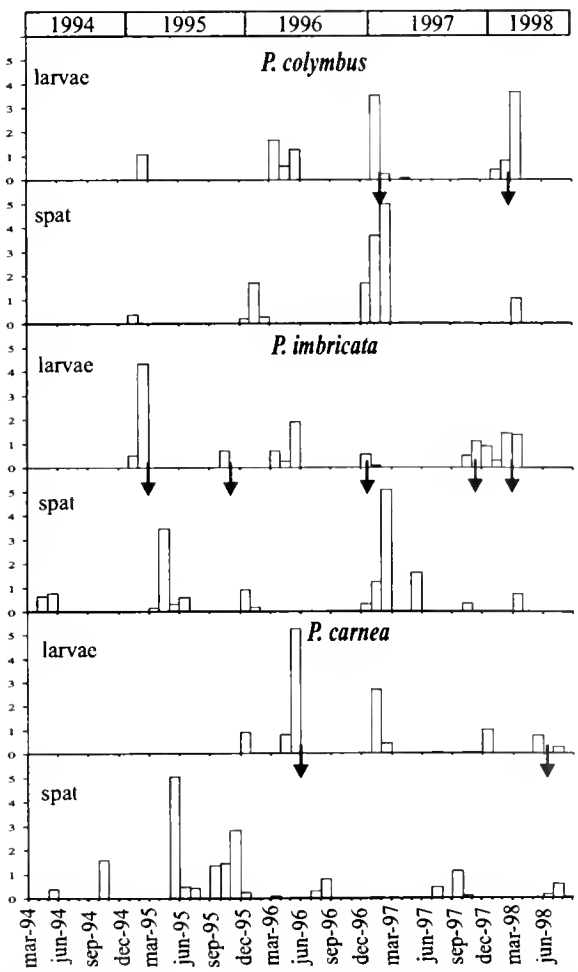

Figure 5. Larval and spat abundance of *Pteria colymbus*, *Pinctada imbricata* and *Pinna carnea*. (Black arrows indicate a good agreement between larvae and spat peaks, i.e., a larvae peak shortly before a spat peak).

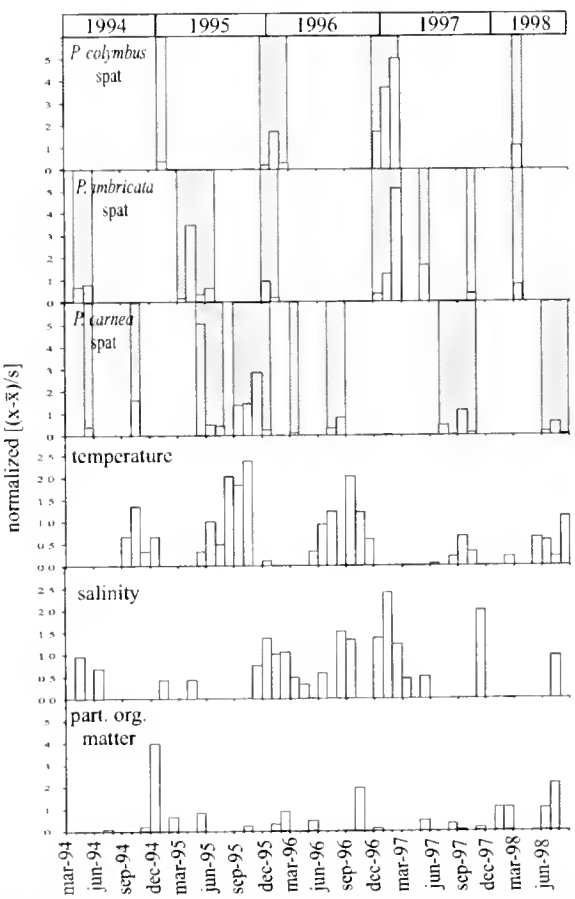

Figure 6. Spat abundance of *Pteria colymbus*, *Pinctada imbricata* and *Pinna carnea* compared with temperature, salinity and particulate organic matter. (Periods of spat peaks are indicated with gray bars).

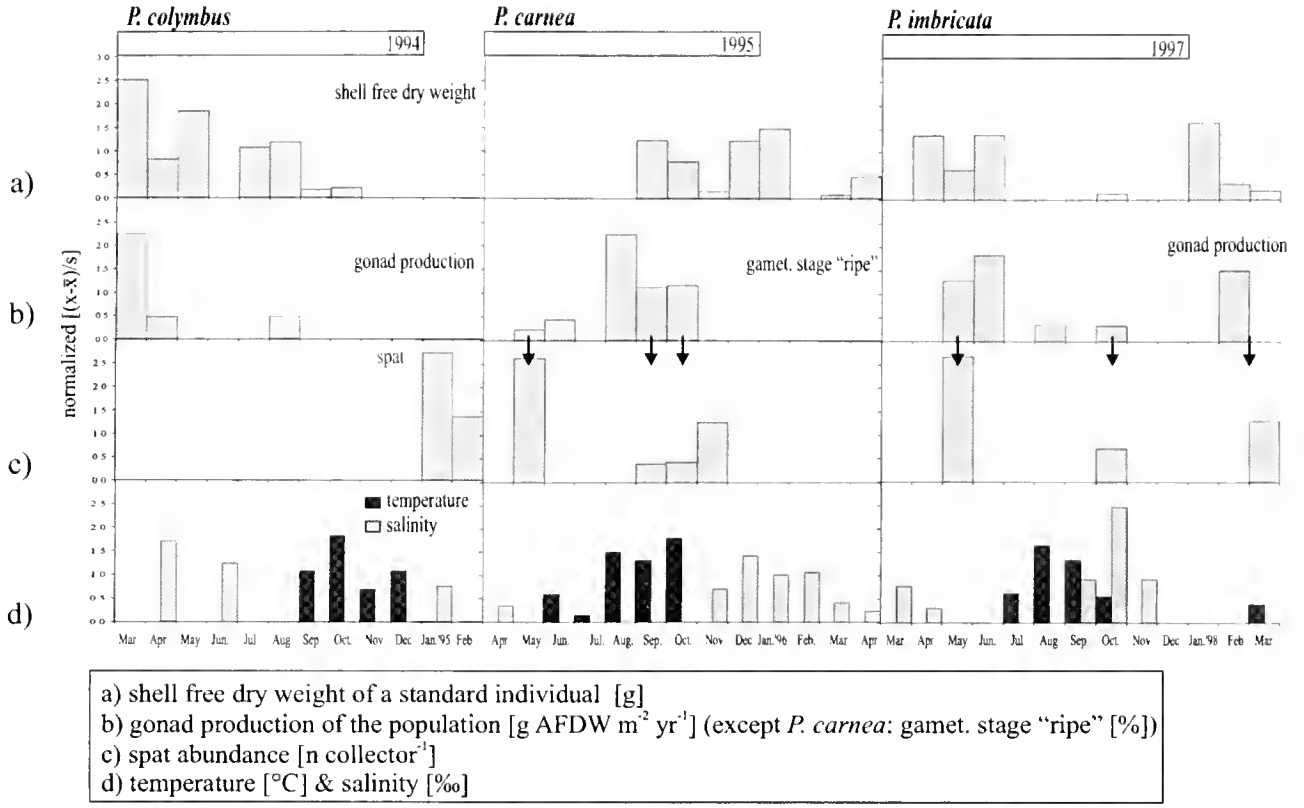

Figure 7. Temporal coupling (black arrows) of gonad production and spat abundance of *Pteria colymbus* (March 1994 to February 1995) *Pinctada imbricata* (April 1995 to April 1996) and *Pinna carnea* (March 1997 to March 1998).

related to particle concentration only up to a certain optimum concentration (Jørgensen 1960, Foster-Smith 1975). Should the POM concentration surpass this optimum no extra surplus energy would be assimilated.

As to discuss reproductive strategies we have three epifaunal filter feeders distributed in the same study area. The principal differences in their niches seem to be substrate preference (*Pteria colymbus*: octocorals, *Pinctada imbricata*: sea grass community, *Pinna carnea*: buried semi-infaunal). They all display continuous reproductive cycles, typical for tropical regions with spent gonads during at least seven months of the year, and larvae as well as spat throughout most of the year. In contrast, for the clam *Gari solida* from Southern Chile (Urban & Campos 1994) and for the Antarctic bivalve *Laternula elliptica* (Urban & Mercuri 1998) more discontinuous reproductive cycles were observed with principally spent gonads present only during 2–3 months of the year.

Apart from common characteristics, this study revealed the following differences: The two closely related pearl oysters (*Pteria colymbus* and *Pinctada imbricata*) show several similarities such as high correlation between larval as well as spat cycles. In comparison, spat cycles of *Pinna carnea*, are not correlated with either of the spat cycles of both oysters. Furthermore, for both pearl oysters temperature is negatively correlated with spat, (and positively correlated with *Pinna carnea* spat). On the other hand, *Pteria colymbus* had only half of the spat peaks, and thus less mean spat abundance along with uncoupling of gonad production and spat cycles that clearly displays differences from *Pinctada imbricata*. Also, gametogenic activity of *Pteria colymbus* is less continuous than the latter two species, because at least during a two-month period (December 1994 to January 1995) little or no spent or ripe gonads were present. Thus, on a scale from discontinuous reproduction of polar species to continuous reproduction of tropical species as the extremes, we would find *Pteria colymbus* in a more intermediate position inclined towards the "tropical group".

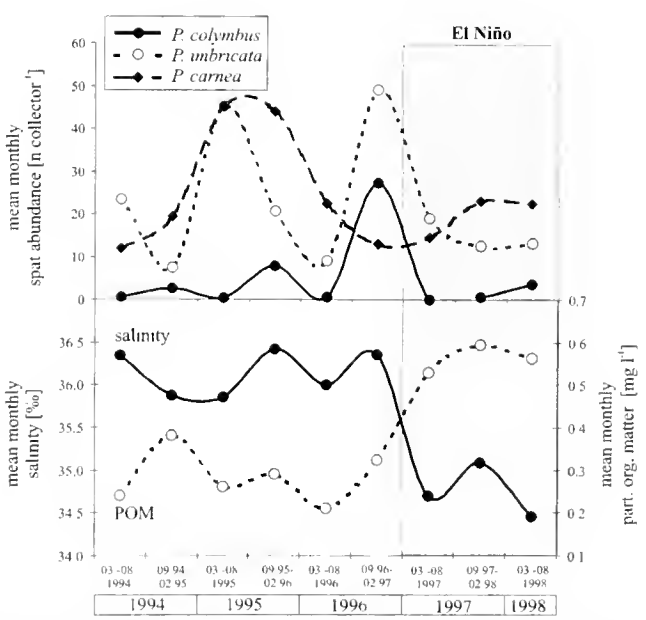

Figure 8. Effects of El Niño on salinity, particulate organic matter and spat abundance of *Pteria colymbus*, *Pinctada imbricata* and *Pinna carnea*. Six months means of original data.

POPULATION STRUCTURE AND RECRUITMENT OF THE BIVALVE *ARCTICA ISLANDICA* (LINNAEUS, 1767) ON GEORGES BANK FROM 1980–1999

CRAIG V. W. LEWIS,[1] JAMES R. WEINBERG,[2] AND CABELL S. DAVIS[3]

[1]*Dept. of Integrative Biology, U.C. Berkeley, Berkeley, California 94720-3140;* [2]*National Marine Fisheries Service, Woods Hole, Massachusetts 02543;* [3]*Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543*

ABSTRACT *Arctica islandica* is a commercially important bivalve from the North Atlantic Ocean. Due to its slow growth rate and longevity, long-term studies are needed to understand its population dynamics, particularly recruitment. This study describes the spatial distribution and population structure of *A. islandica* on Georges Bank, USA from 1980–1999. Results are based on samples collected with a hydraulic clam dredge during National Marine Fisheries Service ocean shellfish surveys. In all surveys from 1980–1999, individuals were abundant on the south flank of Georges Bank between 60 and 75 m depth. In the 1980s, size distributions in tows were typically unimodal, and the population was dominated by large individuals, 75–90 mm in length. In contrast, bimodal size distributions were observed at many stations in the 1990s, and small individuals (<70 mm in length) often represented 20–50% of the catch (by number). These small individuals were the result of spawning in the 1980s. Ages of clams were estimated from shell banding at one station in 1994. Most individuals had less than 40 bands, and individuals between 21 and 28 were rare. Among young individuals, modes were centered on 7 and 12 bands; assuming band formation is approximately annual, this suggests recruitment by cohorts spawned during 1986 or 1987 and 1981 or 1982. These results imply that annual recruitment of small *A. islandica* on Georges Bank has been highly variable during the last 40 years and suggest an increase in recruitment to the fishery after 1990.

KEY WORDS: *Arctica islandica*, Georges Bank, recruitment, growth, population dynamics

INTRODUCTION

The purpose of this study is to provide a comprehensive analysis of the NMFS research survey data collected on the ocean quahog, *Arctica* (=*Cyprina*) *islandica* (Linnaeus 1767), from Georges Bank, USA between 1980 and 1999. Specific goals were to describe the size and age structure, recruitment, individual growth rate and spatial distribution of *A. islandica*. Previous research on *A. islandica* from Georges Bank includes stock assessments (e.g., NEFSC 1990, 1996, 1998), relationships between age and growth (Ropes & Pyoas 1982), and population genetics (Dahlgren et al. 2000).

Arctica islandica is unusual in having one of the slowest adult growth rates among marine bivalves (Turekian et al. 1975, Thompson et al. 1980a, Thompson et al. 1980b, Murawski et al. 1982, Fritz 1991, Kraus et al. 1992). The species is widely distributed along the coasts of the North Atlantic Ocean (Nicol 1951, Merrill & Ropes 1969, Brey et al. 1990, NEFSC 1998, Witbaard et al. 1999). In the United States, a valuable commercial fishery for this species has existed since the 1970s (Murawski & Serchuk 1989, Serchuk & Murawski 1997, NEFSC 1998). In this fishery, the clams are typically harvested between 80 and 100 mm in shell length (NEFSC 1998). A commercial fishery has also developed recently in Iceland (Thórarinsdóttir 1997). Understanding the population dynamics of slow growing species, particularly recruitment, can provide the information needed to determine rates of sustainable exploitation.

Inherent in the measurement of recruitment is the definition of the term *recruitment*. For purposes of this study, an individual is considered to have recruited when it is large enough to be measured in the National Marine Fisheries Service (NMFS) stock assessment survey (this size is approximately coincident with the age of first reproduction (Thompson et al. 1980b) and the size at which individuals are vulnerable to commercial fishing equipment). This functional (and liberal) definition implies that a recruited individual has survived a host of planktonic, settlement and post-settlement hazards. For comparison, the term *settlement* will be used to describe the arrival of a meroplanktonic larvae onto suitable substrate. In *Arctica islandica* the years between settlement and recruitment involve myriad largely unknown risks and processes. Our interest focuses on developing an understanding of the temporal variation in recruitment to the fishery using the NMFS data.

The National Marine Fisheries Service has carried out standard research surveys of *Arctica islandica* off the US east coast since 1980. With the exception of an area south of Long Island, NY (Murawski et al. 1982), there was little evidence of small (50–70 mm) individuals throughout the 1980s (NEFSC 1998); however, the abundance of clams in this size class has always been uncertain because the clam dredge used to collect the survey samples does not retain all of the individuals below 70 mm in length (NEFSC 1998).

The focal region of this study, Georges Bank, has recently become the focus of a major interdisciplinary research project on interannual variability in biological and physical oceanographic processes (GLOBEC 1992). Georges Bank is unique for *A. islandica* because a commercial ocean quahog fishery has not occurred there. This represents an opportunity to characterize population dynamics in the absence of direct fishing pressure. Fishing pressure on groundfish and sea scallops in this region has been intense (NMFS 1999), however, and is likely to have caused indirect mortality to *A. islandica* and other infaunal species (Witbaard & Klein 1994, Bergman & Van Santbrink 2000).

MATERIALS AND METHODS

Study Organism

Arctica islandica is a filter-feeding bivalve common throughout the cold, coastal waters of the North Atlantic. It is the only extant species in its genus, which dates back to the Cretaceous (Nicol 1951, Abbott 1974). It is found along the North American coast from Cape Hatteras in the south, to Georges Bank, the coast of Maine, and Newfoundland in the north (Merrill and Ropes 1969, NEFSC 1998). No extant populations occur off the coast of Greenland (Jensen 1912, Ockelmann 1958). Along the coast of Europe it is found from the White Sea to the Bay of Cadiz, while

the Arkona Sea is the eastern limit in the Baltic (Nicol 1951, Merrill & Ropes 1969, Brey et al. 1990). The species has also been reported from the coasts of Iceland, the Faroes, the Shetlands, the British Isles and Norway (Nicol 1951, Thórarinsdóttir 1997). Along the U.S. coast, *A. islandica* typically occurs at depths of 30 to 75 meters (NEFSC 1998). It is usually found in sand and sand-shell substrates (Fogarty 1981, Thouzeau et al. 1991a,b, Thórarinsdóttir 1997).

Arctica islandica is one of the longest-lived bivalves on the continental shelf, ages of 50–100 years are common in natural populations, and the maximum reported age is approximately 200 years old (Thompson et al. 1980a,b, Murawski et al. 1982, Fritz 1989, Steingrímsson and Thórarinsdóttir 1995).

Rate of growth is relatively fast until the age of 7 years (Thompson et al. 1980a,b). The growth rate of older individuals is among the slowest known for bivalves, with the exception of certain deep-sea species from soft sediments (Turekian et al. 1975, Thompson et al. 1980a, Murawski et al. 1982, Fritz 1991). Ropes and Pyoas (1982) showed that the growth rate of *A. islandica* is faster on Georges Bank than off the coasts of Long Island, NY, USA and Sable Island, Canada. Field studies have shown that among older individuals, females tend to be larger than males (Ropes et al. 1984, Fritz 1991). In the US Middle Atlantic Bight, age at maturity ranges from 4 to 14 years (Thompson et al. 1980b).

Longevity and growth rate determinations have been based on tagging studies and length frequency modal progression (Murawski et al. 1982), as well as on counts of microscopic growth lines within the shell. Numerous studies indicate that these lines are deposited annually and can be used to obtain a reliable estimate of individual age (Jones 1980, Thompson et al. 1980a, Murawski et al. 1982, Turekian et al. 1982, Ropes et al. 1983, Ropes 1984, Ropes & Jearld 1987, Weidman & Jones 1993, Weidman et al. 1994). The exact determination of age from band counts is not always possible because physical disturbances can cause ocean quahogs to produce additional bands (Turekian et al. 1982, Ropes et al. 1983, Ropes 1984, Kraus et al. 1992) and shell wear may result in loss of bands (Ropes 1984).

Data Collection

A stratified random sampling design was used by the National Marine Fisheries Service in surveys to assess stock biomass and size-structure of *Arctica islandica* on Georges Bank (Fig. 1; NEFSC (1998)). Surveys analyzed in this paper were carried out during the summer months of 1980, 1982, 1983, 1984, 1986, 1989, 1992, 1994, 1997, and 1999. A hydraulic clam dredge, 152 cm wide and weighing 3.2 t, was used to collect all samples. The openings in the body of the dredge are 2.5 × 5.1 cm.

Samples of ocean quahogs were collected during surveys by towing the dredge for five minutes at 2.8 km h^{-1} after it made contact with the bottom. The actual distance towed varied between stations due to differences in station depth and winch speed, which affected time to deploy and retrieve the dredge. Actual distance sampled at each station was determined from doppler readings for surveys conducted from 1980 to 1994, and from bottom contact sensors and inclinometers mounted on the dredge in 1997 and 1999.

For analysis, catch at each station was standardized to a common distance of 278 m (i.e., 0.15 nautical miles), assuming a linear relationship between catch per tow and distance sampled. Given the dredge width, this represents an area sampled of 423 m^2 per

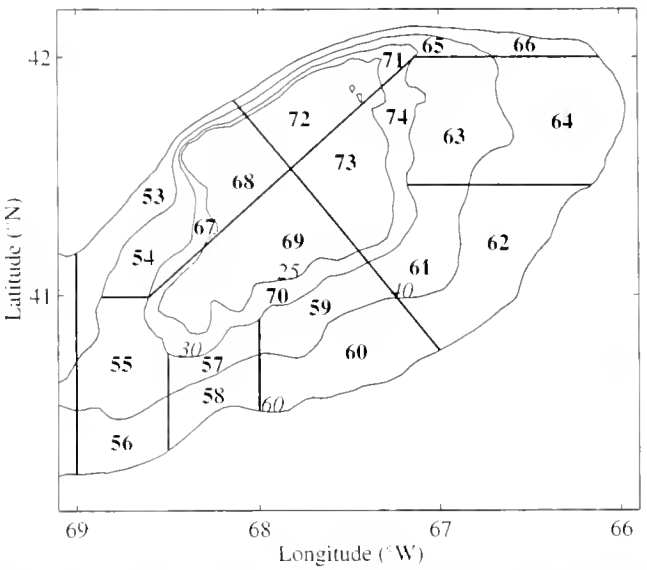

Figure 1. National Marine Fisheries Service ocean shellfish survey strata on Georges Bank. Boundaries of the survey strata are at the 25, 30, 40 and 60 fathom isobaths (1 fathom = 1.83 m). Dotted line indicates the boundary between U.S. and Canadian waters.

standard tow. This is a conservative estimate of the true density, as the dredge is likely to pass over and destroy some clams (Smolowitz & Nulk 1982). In addition, the dredge has only partial retention of ocean quahogs that are <70 mm in shell length (NEFSC 1998, 2000); while specimens much smaller than the mesh size are frequently retained in the sample, their retention is likely to be very unreliable. Additional details about the clam dredge and sensors are given in Smolowitz and Nulk (1982), and NEFSC (1998).

All live ocean quahogs at each station (i.e., tow) were counted and shell lengths, defined as the maximum anterior to posterior distance in mm, were measured at sea to compute average size-frequency distributions per tow for each stratum.

In 1994, a bimodal size structure was noted in several tows on the south flank of Georges Bank (Lewis 1997). The existence of numerous small (<70 mm) clams implied a surge in recruitment to that area. To estimate when these ocean quahogs were spawned, a random subsample of 144 individuals (from a total of 883) was taken from Station 448 in Stratum 61 (41°9′N and 67°1′W) for age estimation based on counts of internal bands. Shell lengths were also measured to estimate growth rate.

The procedure for determining age involved several steps. Each clam was labeled and a valve was selected for sectioning. No preference was given to right or left valves. Shells were sectioned with a glass-cutting saw from the umbo to the most distant portion of the shell. The cut edge was polished on Buehler Polimet Polisher and glued to a microscope slide. A Buehler Isomet 11-1180 Low Speed Saw was used to cut most of the shell away from the slide, leaving a 600–800 μm thin section embedded in epoxy. Sections were ground to 250–300 μm on a Ingram Laboratories Model 305 Thin Section grinder and polished to 150 μm.

To determine clam age, shell bands in prepared sections were counted at least twice per individual using a microscope at ×25 magnification. In the present study, counts of bands were used to indicate age-structure of the population, even though estimated age may not be exact for every individual in the sample. In most cases, an underestimate of age is likely. This is due to the timing and

placement of the year 1 band which is deposited only 3 to 6 months after settlement in a region of the shell that shows heavy abrasion. While not accounted for in our growth calculations, this adds further ambiguity to exact estimates of age.

Age and Length Structure Analysis

A major purpose of the present study was to detect recruitment into the population as indicated by the existence of multiple modes in size- and age-distributions in the NMFS survey data. We used a randomization procedure (Silverman 1981, 1983; Efron & Tibsherani 1993) to statistically test each observed size- and age-distribution for the presence of multiple modes. The test statistic was the minimum value of a smoothing kernel width, h_1 (referred to as "window size"), that would smooth the sampled frequency distribution until there was only one mode or local maximum. A large value of h_1 is required to smooth a distribution with strong and widely separated peaks.

The value of h_1 from the observed data was compared to a probability density function generated by calculating h_1' for each of a large number of bootstrap samples from the original data. The null hypothesis: H_0: number of modes = 1, was rejected if the probability of finding h_1 greater than h_1' was greater than or equal to 0.95.

In cases where the null hypothesis of one mode was rejected, the procedure was repeated, calculating h_2, a window size that generated 2 modes, with a new set of bootstrap samples based on that window size. In general, if the null hypothesis, H_0: number of modes = k, was rejected, then the hypothesis, H_0: number of modes = $k + 1$, was tested.

The exact procedure for the bootstrap involved a number of numerical steps. The minimum value of h such that the function,

$$f(t; h) = \frac{1}{nh} \sum_{i=1}^{n} \phi\left(\frac{t - x_i}{h}\right) \qquad (1)$$

has only one mode or local maximum ($\phi(t)$ is the standard normal density), was determined by successive approximation (values of x_i refer to length, to the nearest mm, or age, in years, of individual clams selected from among the n clams in a given tow). This minimum value was the test statistic, h_1.

Each bootstrap sample contained n individuals drawn at random from the smoothed distribution of the original data following the methods of Efron and Tibshirani (1993). In all tests conducted here, the distribution of h_1' was based upon 200 bootstrap samples. First, n individual values, $y_1' \ldots y_n'$, were sampled, with replacement, from the original data set, $x_1 \ldots x_n$. The values of the n members of the bootstrap sample were calculated from the y' values using the formula:

$$x_i' = \bar{y}' + \sqrt{1 + \frac{h_1^2}{\sigma^2}}\,(y_i' - \bar{y}' + h_1 \epsilon_i); \; i = 1, 2, \ldots, n \qquad (2)$$

where $\bar{y}'$ was the mean of the y' values, σ^2 was the variance of the original sample, x, and the ϵ_i were standard normal random variables. In practice, rather than determine the exact value of h_1 needed to generate a smoothed bootstrap sample with one mode, it was only necessary to know whether h_1' was greater than or less than h_1 for each bootstrap sample. If $P(h_1' > h_1) > 0.05$ (10 out of 200 bootstrap samples), then the null hypothesis was rejected and the alternative hypothesis, that there was more than one mode, was accepted. Otherwise, if $P(h_1' > h_1) \leq 0.05$, the null hypothesis that there was only one mode was accepted.

The statistical test for multiple modes in a frequency distribution was carried out on the observed size-frequency data at each station from Georges Bank. In addition, the test was applied to the observed age-frequency distribution at Station 448 in Stratum 61, defining the x values as the number of shell bands per individual.

RESULTS

Arctica islandica were concentrated around the periphery of Georges Bank, with greatest concentrations on the south flank between 60 and 75 meters depth (Fig. 2 and Fig. 3). Moderate densities of ocean quahogs were found on the steep north flank between 50 and 100 meters depth. Relatively few ocean quahogs were collected from shallower stations located near the center of the Bank (Fig. 3). On the south flank, *A. islandica* were present at almost all stations between 50 and 80 meters depth. The deep water limit for the species was not completely resolved by these surveys, although samples taken at depths greater than 90 meters contained very few individuals (Fig. 2 and Fig. 3).

From the 1980s to the 1990s there were changes in size structure of the population on Georges Bank that were suggestive of an increase in recruitment. In the 1980s, the size structure within most strata was unimodal and dominated by large, 75–90-mm, individuals. In contrast, the size-frequency distributions from 1992 to 1999 contained large individuals as well as numerous (i.e., tens to hundreds) small clams, 40–70 mm in length. The dredge limitations make it difficult to assess the magnitude of the recruitment, but the consistency of the observations over several regions and years provide strong support for the hypothesis that the observations are more than a mere sampling artifact. The data from 1982–1984 and 1994 (Fig. 4) demonstrate typical size frequency distributions from surveys in the 1980s and 1990s, respectively.

The appearance of small individuals in the 1990s was widespread along the south flank of Georges Bank, including Strata 57, 59, 60, and 61 (Fig. 1, Fig. 5, and Fig. 6). This increase in small clams was unlikely to be a sampling artifact because the same dredge, bar spacing, and mesh liner were used throughout the

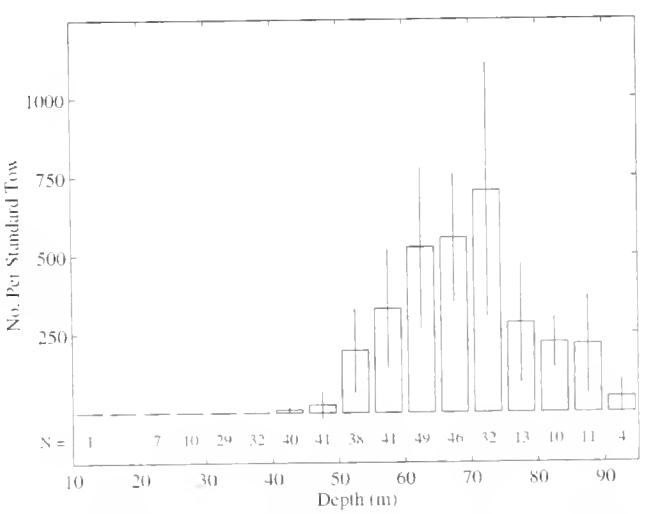

Figure 2. Mean (bar) and 95% confidence interval for number of *Arctica islandica* per standard tow, in five meter depth intervals for all representative tows on Georges Bank from 1980–1999. Number of tows taken within depth intervals is shown at bottom of the bar.

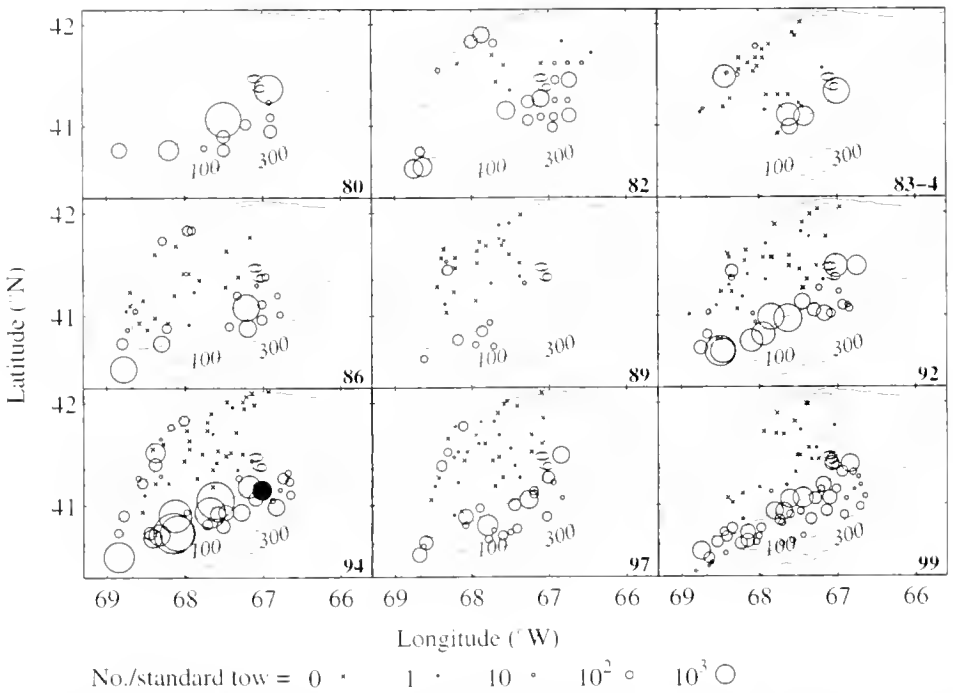

Figure 3. Number of *Arctica islandica* per standard tow from the 1980–1999 survey cruises. Area of circle is proportional to catch, in numbers. The station at which age frequency sampling was performed in 1994 is designated by a filled circle. Isobaths are in meters.

study. In the 1990s, the percentage of small (<70 mm in length) ocean quahogs per sample often ranged from 20–50% (Fig. 6). These percentages are minimum estimates for the actual population structure because the dredge has partial selectivity for ocean quahog shells <70 mm.

The data (Fig. 5) also suggested that level of recruitment varied between strata. For example, a group of small (30–45 mm long) individuals was common in Stratum 59 in 1997, but this group was not as abundant in adjacent Stratum 61.

Statistical tests confirmed that population structure changed over time. Specifically, we tested whether the ocean quahog catch from each tow from 1980 to 1999 satisfied three criteria that suggest recent recruitment. The three criteria were: (1) the statistical test of multimodality had to be significant, (2) at least one of the modes had to be centered below 70 mm in length, and (3) abundance of small (<70 mm) clams had to exceed 20 clams per standard tow. This criterion was for statistical and not ecological significance, making the test more rigorous by eliminating tows that captured a low number of individuals. This represents an abundance far below what would be expected in a stable or expanding population (however, the abundance as measured by the dredge is believed to be less than the actual number in the swept area). Of the 404 tows from all 10 surveys, 71 of the size-frequencies had two or more modes; 59 of those had a lower mode centered below 70 mm, and 34 of those had a sample density of at least 20 small clams per standard tow. Among these 34 tows, 32 (94%) were taken on the south flank between 1992 and 1999 (Fig. 7). Only two of the tows that satisfied all three criteria were collected in the 1980s (Fig. 7). The proportion of tows over the entire bank that satisfied all three criteria went from 0.014 in the 1980s to 0.124 in the 1990s. The proportion of tows that satisfied all three criteria was significantly greater in the 1990s than in the 1980s (χ^2 test: $p < 0.001$). If the statistical test is restricted to data from the south flank (Strata 57–62), where most of the recruitment took place, then the test result is even more significant (Table 2).

The ability to detect recruitment is affected by the intensity of sampling in the 1980s and 1990s. A total of 146 tows from the 1980s were tested for satisfying the three criteria, compared to 258 tows from the 1990s.

The size-based results motivated a study to identify the ages of individuals that recruited to the surveyed population in the 1990s and to infer whether such recruitment was continuous or irregular in time. The sample from Station 448 was composed of two major age groups (Fig. 8), one with individuals younger than 21 years and another with ages of 28 years and greater. Of the 144 clams in the sample, 7 individuals were over 40 years old, ranging in age from 48 to 101 years.

Most of the clams greater than 70 mm in length were at least 11 years old (Fig. 9). This roughly identifies the age at which ocean quahogs from Georges Bank are fully selected (i.e., retained) by the NMFS clam dredge. Extrapolating from the data collected at Station 448, it would appear that most of the clams on Georges Bank that range in length between 70 and 100 mm are 11 to 45 years old. One clam with over 100 bands was found in the sample, but too few clams were sampled in the percent study to determine the maximum age of ocean quahogs on Georges Bank.

To infer which year classes are responsible for the observed recruitment peak in Stratum 61, the test for multiple modes was applied to the age frequency data for ages less than 15 years (Fig. 8). The hypothesis that this group had only one mode was rejected ($p < 0.005$), but the hypothesis that the group had two modes was not rejected ($p < 0.05$). The 2 modes were centered around 7 and 12 bands. Given that the clams were collected in 1994, this would indicate larval settlement by these groups in about 1987 and 1982. Due to the fact that number of bands may not be exactly equal to age (see Methods), we cannot determine from the data whether

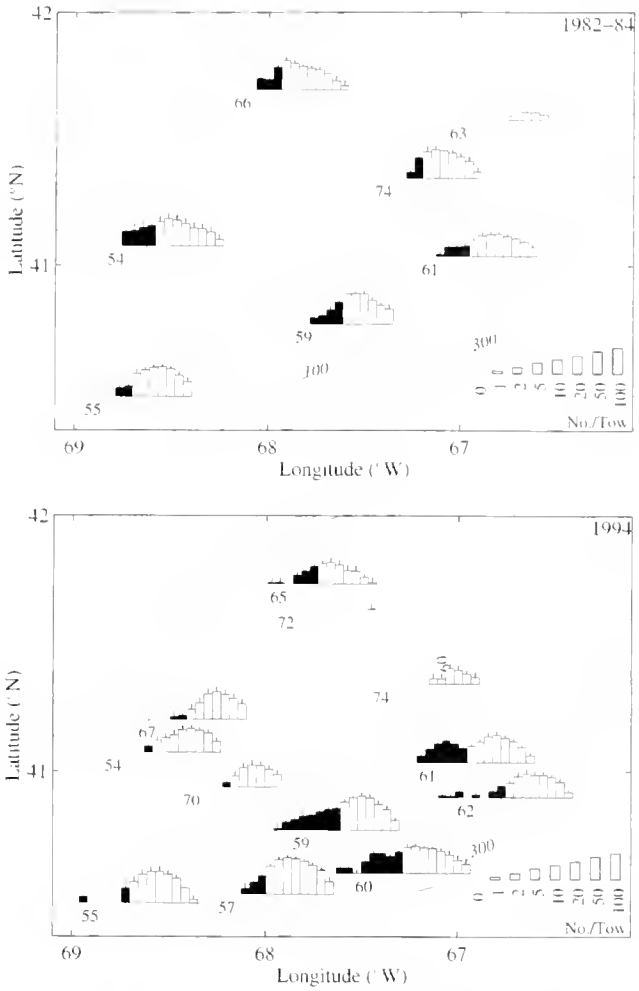

Figure 4. Size structure of *Arctica islandica* by stratum (for strata in which more than one tow was made) over time. Numbers below each histogram denote the stratum number. Individual graphs show the log of the mean (bars) and upper 95% confidence interval (line) for abundance in each size class from 40 to 110 mm, in 5 mm intervals. Size classes smaller than 70 mm are shown in black to highlight the presence of small individuals; dots indicate that no clams in those size classes were recorded.

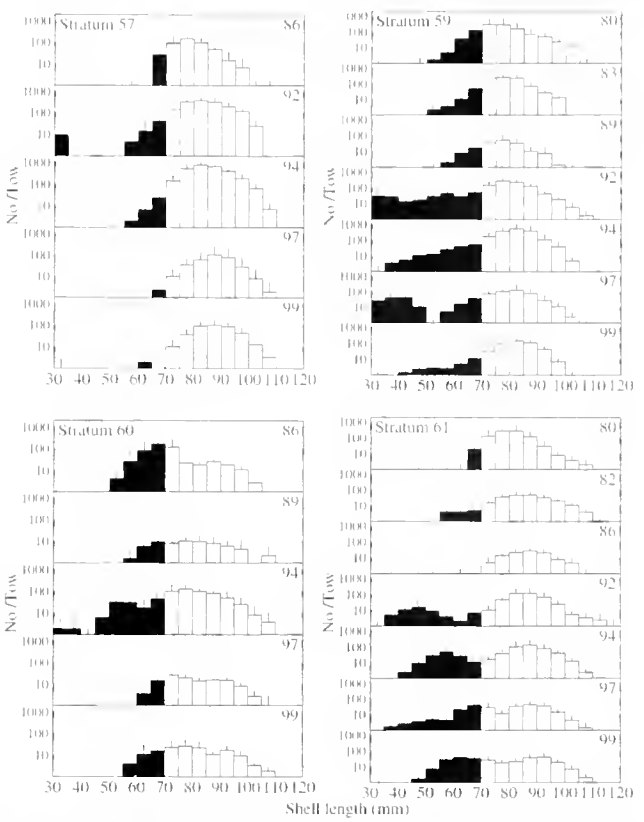

Figure 5. Size structure of *Arctica islandica* in four strata from the south side of Georges Bank, 1980–1999. Graphs show mean (bars) and upper 95% confidence interval (line) for indicated years. Size classes <70 mm are shown in black to highlight the presence of small individuals.

each period of successful settlement lasted for only one year or multiple years.

On Georges Bank, *Arctica islandica* reaches adult size fairly early in its life span (Fig. 10 and Table 1). Individuals grow faster on Georges Bank than in other regions for which growth curves exist. In the 1994 age sample, clams possessing 11–14 bands had an average length of 69.2 mm. The three clams with over 70 bands were smaller than some with a few as 29 bands, implying high variability in growth rate among individuals. An abrupt transition in band structure, from broad (5–10 mm) to narrow (~1 mm) spacing between successive bands, occurred between 7 and 10 bands, implying a shift from relatively rapid juvenile growth to slow adult growth.

DISCUSSION

Several mechanisms may explain the distribution of *Arctica islandica* on Georges Bank between 60 and 90 meters. At these depths, stratification is rarely broken down by tidal mixing. Hence, bottom water temperature is typically cooler and there is lower seasonal variation than in the shallow tidally mixed region within the 60 meter isobath (Flagg 1987). On the south flank, the highest survey catches were recorded near the 60 meter isobath, roughly corresponding to the location of a convergent front that defines the boundaries of the stratified Shelf Water with the tidally mixed Georges Bank Water. This front may serve to accumulate upward swimming larvae at the surface (Mann & Wolf 1983, Franks 1992).

Adult ocean quahogs have low survival at water temperatures greater than 20 C (Turner 1949, Nicol 1951, Landers 1976). Occasional high temperatures in the well-mixed central bank water may be sufficient to exclude *Arctica islandica* from this region. Furthermore, tidal currents over the central bank consistently resuspend sediments which may overwhelm the feeding capability of this filter-feeding bivalve. Finally, competition between *A. islandica* and the Atlantic surfclam, *Spisula solidissima*, may favor the latter in the shallow waters. The distributions of these two species are complementary throughout the Middle Atlantic Bight, with *A. islandica* found in cooler, deeper water (NEFSC 1998). The differing thermal tolerances of the two species are a likely factor in their segregation.

The results suggested that *Arctica islandica* recruit on Georges Bank on an irregular basis. *A. islandica* populations may survive for long periods of time even if recruitment occurs infrequently because of this species' longevity and iteroparous reproductive

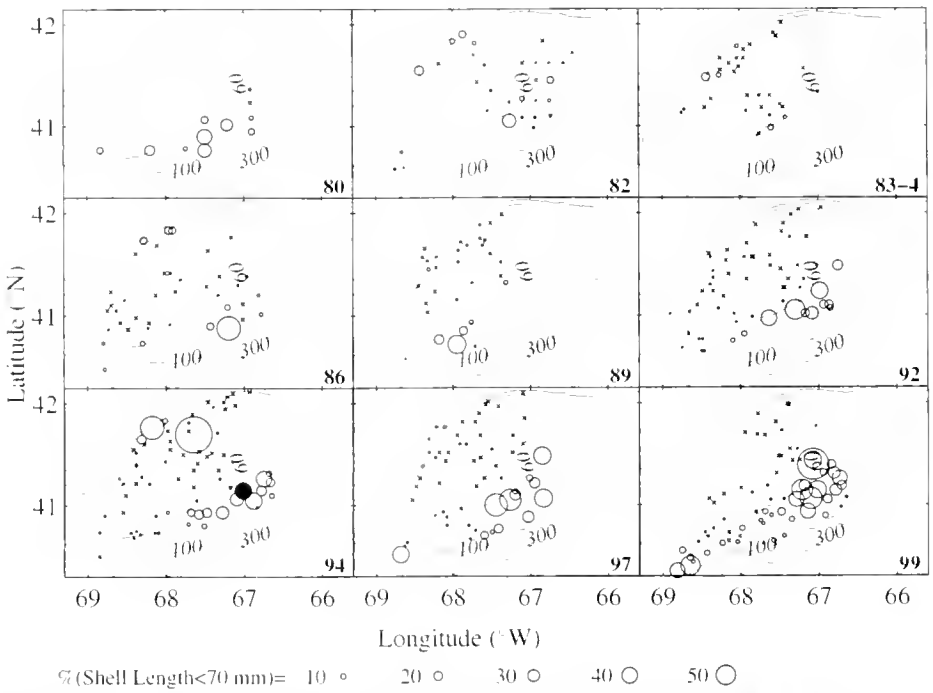

Figure 6. Percent of catch that was smaller than 70 mm in each tow from the 1980–1999 survey cruises. Radius of circle is proportional to percentage (the very large circle in 1994 reflects the presence of a single small clam at the station). Isobaths are in meters.

mode. It is difficult to identify the exact timing and nature of large recruitment events because the ocean quahogs on Georges Bank are not fully retained by the dredge until they are about 70 mm in shell length or about 10 years old. At the station where age-structure was determined, there were apparently 2 major cohorts that settled during the 1980s. In contrast, the absence of individuals between the ages of 21 and 28 in 1994 suggests that little recruitment took place from 1967 to 1974. The high variability in the age structure sample (Fig. 1) also suggests highly intermittent recruitment at this site.

Compared to *Arctica islandica*, shorter-lived and faster-growing bivalves appear to recruit more frequently and with less variation in recruitment strength (Tremblay & Sinclair 1990, Tremblay & Sinclair 1992). Research on two large bivalves from Georges Bank, *Spisula solidissima* and sea scallop (*Placopecten magellanicus*), provides an interesting contrast with *A. islandica*.

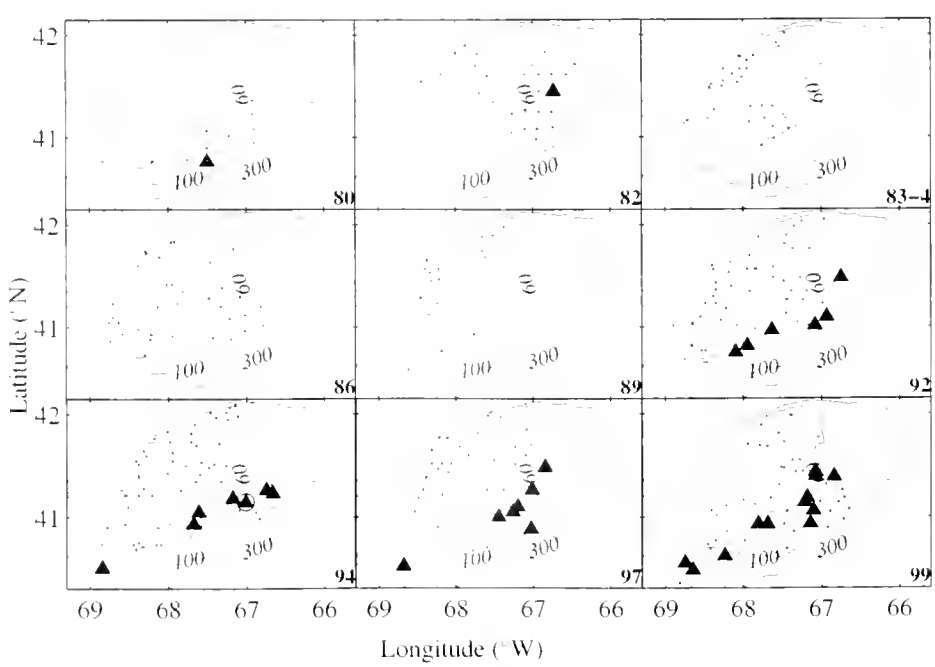

Figure 7. Location of all tows in which two or more modes were detected in the size structure (triangles) for each year, the lowest mode was centered below 70 mm, and density of all individuals less than 70 mm was greater than 20 per standard tow. Isobaths are in meters.

L = length; a = age

S. solidissima has a maximum lifespand of approximately 35 years (Weinberg 1999) and *P. magellanicus* appears to live for 10–15 years (Thouzeau et al. 1991a, Thouzeau et al. 1991b), which makes both species short-lived compared to *A. islandica*. *S. solidissima* recruited successfully along the US Atlantic coast in most years from 1978 to 1997 (Weinberg 1999). Several studies have detected distinct peaks in the size structure of *P. magellanicus* surveyed on Georges Bank, indicative of good annual recruitment (Serchuk et al. 1979, Serchuk and Wigley 1986, Thouzeau et al. 1991a, McGarvey et al. 1993). Given low mortality levels, a long-lived species such as *A. islandica* can maintain viable population levels without recruitment for many years, whereas shorter-lived species require recruitment to prevent extinction.

Many studies report that long-lived species have slow individual growth rates, and exhibit low resilience to and slow recovery from overexploitation (Musick 1999). Although there has been a significant commercial fishery for *Arctica islandica* in the U.S. Middle Atlantic Bight since 1980 (NEFSC 1998), the population on Georges Bank has not been exploited yet commerically. Nevertheless, several major fisheries (e.g., scallops, ground fish) have taken place on Georges Bank throughout the 1980s and 1990s (NMFS 1999). Fish trawls impact the benthic community, causing substantial mortality in bivalves such as *Spisula* sp. and *A. islandica* in the North Sea (Bergman & Van Santbrink 2000). Thus, the changes in population structure of *A. islandica* over time reported in the present study are probably representative of population dynamics under conditions of low to moderate human disturbance.

We have not determined which biological and physical factors control recruitment of *Arctica islandica*. We have examined sea bottom temperature records from Georges Bank (Holzwarth & Mountain 1990), and there is no obvious relationship between observed recruitment and temperature at time of settlement. Other factors which are potentially important include predation, spawning success, availability of larvae, and habitat quality on the sea floor. Potential predators on newly settled clams include various groundfish, such as winter flounder (Steimle et al. 1994), sea stars (Franz et al. 1981), cancer crabs, and the gastropods *Lunatia* and *Busycon*.

Mann (1982, 1985, 1986) provided a complete review of *Arctica islandica*'s larval ecology in southern New England and on Georges Bank. Although the spawning period is prolonged, there may only be narrow windows in time when oceanographic conditions allow for high larval survival and settlement. Mann (1982) hypothesized that phytoplankton becomes available as a major food for *A. islandica* larvae only after wind and storm events mix the stratified water column. It was further suggested that there was

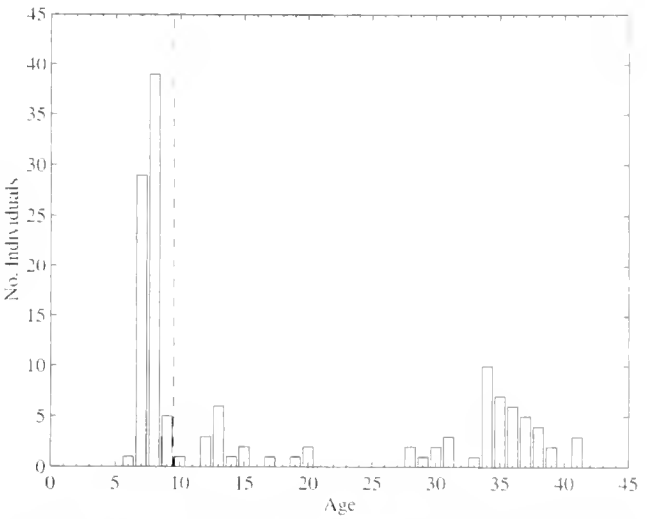

Figure 8. Age structure of ocean quahogs from Station 448 (Stratum 61, 1994 survey), from which a sample of 144 individuals were sectioned for age determination. Dashed line shows approximate minimum age that may to be undersampled by the dredge because of their small size. Seven individuals (not shown) were over 45 years old.

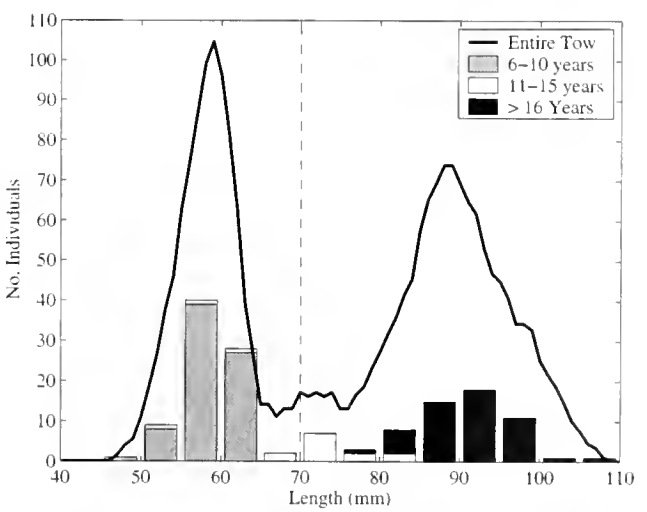

Figure 9. Size structure (for station #448, 1994 clam survey) for all individuals 6–10 (gray), 11–15 (white) and over 16 (black) years old. The shaded bars indicate the size structure of the subsample analyzed for age structure; the dark line shows the measured size distribution of the entire catch (883 individuals) from that tow (smoothed with a 5-mm moving average).

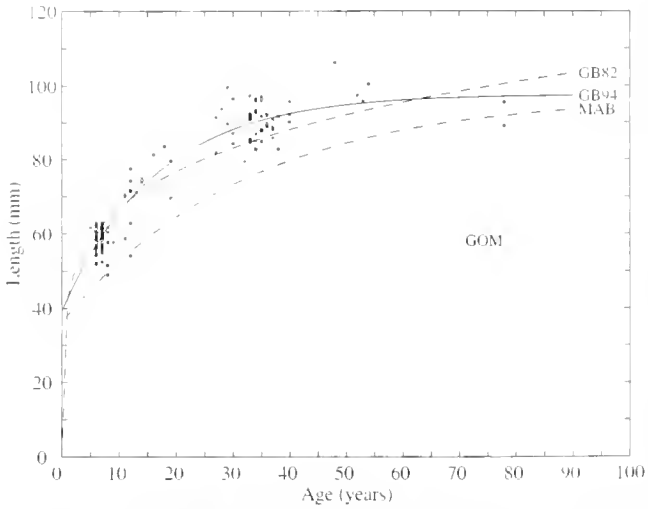

Figure 10. Relationships between age and shell length in *Arctica islandica*. Solid line (GB94): a Von Bertalanffy curve fit to the data ("x") collected in 1994 for the present study of Georges Bank. Dashed line (GB82): a power exponential curve from Ropes and Pyoas (1982) for George Bank. Dash-dot line (MAB) a von Bertalanffy curve from the coast of New York, Middle Atlantic Bight, from NEFSC (1990, 1996). Dotted line (GOM): a curve from a sample in the Gulf of Maine from Kraus et al. (1992). See Table 1 for equations of the growth curves.

no single spawning stimulus; rather temperature, oxygen saturation, pH, and food availability all probably have an effect on spawning time (Mann 1982).

Bottom characteristics vary greatly among different parts of Georges Bank. The south flank, where *Arctica islandica* are plentiful, is composed of poorly sorted gravel, sand and mud. Larger rocks and drifting sand waves, common on the center of the Bank, are relatively rare on the south flank. From a physical standpoint, the south flank is a stable habitat for *A. islandica*.

The population structure of *Arctica islandica* on Georges Bank differs from other regions. For example, compared to populations in the US Middle Atlantic Bight (New Jersey to Virginia), the population on Georges Bank in the 1990s had a higher ratio of small individuals (NEFSC 1998). This is consistent with the results showing that recruitment, as indicated by increased numbers of small individuals in samples, increased on Georges Bank in the 1990s.

Comparisons between growth curves indicate that *Arctica islandica* grows faster on Georges Bank than off the coasts of New York (Murawski et al. 1982), Maine (Kraus et al. 1992), and Iceland (Steingrímsson & Thórarinsdóttir 1995). It is likely that the faster growth of *Arctica islandica* on Georges Bank reflects the region's high productivity (O'Reilly et al. 1987, Backus & Bourne 1987). The experimental work of Kraus et al. (1992) in Maine demonstrated high phenotypic plasticity in the growth rate of this species. In addition, Dahlgren et al. (2000) determined the sequence of the mitochondrial cytochrome b gene of *Arctica islandica* and found little genetic subdivision between Nova Scotia, Canada, and Georges Bank and Virginia, USA. Growth rate in bivalves is affected by many environmental factors, and species may respond differently to these factors due to interspecific differences in physiology and feeding ecology. For example, Weinberg and Helser (1996) compared the growth rate of Atlantic surfclams on Georges Bank with that in other regions along the coast of the U.S. In contrast with *A. islandica, Spisula solidissima* on Georges Bank were smaller at any given age than in warmer regions to the south, closer to the center of *S. solidissima*'s range (Weinberg & Helser 1996).

ACKNOWLEDGMENTS

We appreciate the hard work on the part of the captain, crew and scientists aboard the NMFS Shellfish Assessment cruises while carrying out the NMFS clam surveys, with special thanks to the *R/V Delaware II*. We are grateful to Andy Solow for assisting with the statistical analyses and to S. Murawski, R. Mann, and F. Serchuk for reviewing the manuscript. Portions of this work were sponsored by a WHOI Coastal Research Center Grant and U.S. GLOBEC funding to C. Lewis. This is U.S. GLOBEC Contribution Number 184.

SHORT-TERM EFFECTS OF COMMERCIAL CLAM (*MYA ARENARIA* L.) AND WORM (*GLYCERA DIBRANCHIATA* EHLERS) HARVESTING ON SURVIVAL AND GROWTH OF JUVENILES OF THE SOFT-SHELL CLAM

BRIAN F. BEAL[1]* AND KENNETH W. VENCILE[2]

[1]*University of Maine at Machias, 9 O'Brien Avenue, Machias, Maine 04654;* [2]*Beals Island Regional Shellfish Hatchery, P.O. Box 83 Beals, Maine 04611*

ABSTRACT In Maine, USA, commercial fisheries for soft-shell clams, *Mya arenaria* L., and blood worms, *Glycera dibranchiata* Ehlers, occur simultaneously on muddy intertidal flats. Local and state clam managers frequently close flats to shellfishing for conservation purposes, but have no jurisdiction over wormers who are legally permitted to harvest *G. dibranchiata* on any intertidal flat. This sometimes causes conflicts, especially when wormers dig in clam conservation areas where clammers have enhanced stocks with wild or cultured "seed" clams (<1 cm shell length, SL). Clammers believe wormers kill or injure small clams directly or indirectly while commercially harvesting *G. dibranchiata*. To help resolve these long-standing conflicts, we worked collaboratively with clammers and wormers and used an experimental approach to test the short-term interactive effects of clam and worm harvesting, harvesting intensity, time of harvest after seeding, and predator exclusion on the fate of small wild and cultured *M. arenaria* at an intertidal mud flat in Brunswick, ME. We added 50 cultured juveniles of *M. arenaria* (SL = 12.5 mm) to 120 1-m^2 plots, 40 of which were undisturbed controls (20 protected with plastic netting—6.4 mm aperture; 20 unprotected) from May to August 1996. The remaining 80 plots were assigned to one of 16 treatments. One half of the plots were protected from predators with the same plastic netting used in the undisturbed control plots. One half of the plots were harvested by a professional wormer or clammer who searched each plot for commercial size blood worms and soft-shell clams, respectively. Plots were harvested either once (after two weeks or four weeks) or twice (two weeks + two weeks, or four weeks + four weeks). Any effect due to clamming or worming on cultured clams or wild individuals of similar size was masked by clam losses exceeding 95% in the unprotected control plots. Intense predation by horseshoe crabs, *Limulus polyphemus* L. and the nemertean worm, *Cerebratulus lacteus* Leidy, are blamed for the high mortalities among clams. Only in protected plots was any effect detected and this depended on clam origin. Compared to the fate of cultured clams in protected controls, worming had no effect, but clamming contributed an additional 15% loss. Both types of commercial harvesting reduced wild clam numbers significantly compared to controls, but effects due to worming were more benign than effects due to clamming probably because wormers excavate less volume of sediments than clammers do as commercial size *G. dibranchiata* are shallow burrowers compared to commercial size *M. arenaria*. Unless clam managers actively take steps to deter predators by using netting or other means, blood wormers should continue to harvest commercially from areas closed to shellfishing without reprisal or fear that they are causing damage to populations of juvenile soft-shell clams.

KEY WORDS: blood worm, commercial harvesting, field experiment, fisheries conflicts, *Glycera dibranchiata*, intertidal, Maine, *Mya arenaria*, soft-shell clam

INTRODUCTION

Soft-bottom, unvegetated intertidal flats throughout the world provide habitat for commercially important infauna such as bivalves and polychaetes (Jackson & James 1979, Emerson et al. 1990, Olive 1992, Brown & Wilson 1997). Harvesting these groups of organisms using hand-held implements such as forks, hoes, rakes, or shovels (Creaser et al. 1983, Wallace 1997) or mechanical devices operated during tidal inundation (van den Heiligenberg 1987, Spencer et al. 1998) erodes or removes sediments to some depth below which the fauna reside. Clam digging, for example, causes sediments to become coarser and to lose significant amounts of organic matter compared with undisturbed intertidal areas (Anderson & Meyer 1986). Effects of turning over sediments on mudflat residents may depend on size and geographic extent of the fishery, sediment grain size, depth to which sediments are excavated, time of year, ability of organisms to evade harvesting or reburrow, or combinations of these factors. When the commercial species are shallow burrowers (e.g., venerid clams such as *Mercenaria mercenaria* [L.] or *Tapes philippinarum* [Adams & Reeve]), local impacts on dynamics of the target fishery such as individual growth and recruitment may not be very long lasting; however, changes in habitat may affect negatively nontargeted infaunal or epifaunal populations (Peterson et al. 1987, Hall & Harding 1997, Spencer et al. 1998). Harvesting deeper burrowing organisms (e.g., polychaetes such as lugworms, *Arenicola marina* [L.] [Cryer et al. 1987, Beukema 1995], and sandworms, *Nereis virens* Sars, [Brown & Wilson 1997], or bivalves such as geoducks, *Panopea abrupta* [Conrad] [Campbell et al. 1998]) can have profound effects not only on the unharvested portion of the population, but also on benthic community structure.

In Maine, two intertidal fisheries occur simultaneously. Soft-shell clams, *Mya arenaria* L., are ubiquitous in soft sediments ranging from gravel and sand to soft mud (B. Beal, pers. obs.). *M. arenaria* is harvested for human consumption and is either processed (shucked) for chowder and fried clam markets or sold live to be eaten after steaming (Ellis & Waterman 1998). In 1999, 1,035 metric tons (t) worth $10.5 million were harvested commercially from Maine flats (NMFS 2001, http://www.st.nmfs.gov/st1/commercial/annual_landings.html). Clams ≥50.8 mm (2 inches) in shell length (SL) are harvested using short-handled hoes with 4 to 6 curved tines that are 30 to 38 cm in length (Robinson & Rowell 1990). The depth that commercial-size animals burrow to is typically ≥15 cm, but this depends on SL (Zwarts & Wanink 1989, Zaklan & Ydenberg 1997) and sediment type (Glude 1954). Blood worms, *Glycera dibranchiata* Ehlers, are typically found in muddy sediments where they are excavated for bait using hoes similar in appearance to those used by clammers, except the tines are shorter, ranging from 20 to 25 cm (Dow & Creaser 1970, Creaser et al. 1983, B. Beal, pers. obs.). In 1999, 233.5 t worth

*Corresponding author: E-mail: bbeal@maine.edu

$2.9 million were harvested commercially in Maine (NMFS 2001). Although both clammers and wormers ply their trade on muddy flats, digging style differs between the two groups. Clammers usually seek areas of flats where relatively large, oval-shaped holes (that form when animals extend their siphons above the sediment-water interface to feed during tidal inundation) are visible and numerous (B. Beal, pers. obs.). Adults of *M. arenaria* frequently are distributed contagiously (either due to post-settlement processes that tend to move animals toward the upper intertidal [Matthiessen 1963, Emerson 1990] or to harvesting activity that redistributes sub-legal size animals). Clammers, therefore, tend to move from place to place and dig where they notice an abundance of siphon holes. Thus, clam digging is more intense in some portions of the flats than in others. Generally, there is no regular pattern of sediment excavation in the harvested areas (B. Beal, pers. obs.). Conversely, although *G. dibranchiata* can prey on small fauna at or near the sediment surface (Ambrose 1984) and may leave characteristic surface marks or holes (B. Beal, pers. obs.), these are largely ignored by bait worm diggers who collect the worms as they turn over sediments systematically leaving row after row of disturbed mud (Creaser et al. 1983, Brown 1993). Depending on worm density, some flats may be turned over three or more times during the summer months, whereas most clam flats may be turned over twice, but usually only once per year (Brown and Wilson 1997, B. Beal, pers. obs.).

Historically, flats were harvested for worms or clams, not both. Rarely did participants in the two fisheries dig side by side. Flats harvested for worms contained too few commercial size clams or sediments were considered too soft to maneuver within easily for most clammers (D. E. Wallace, pers. comm.). However, as wild clam stocks in Maine fell during the 1980s and price per bushel (approximately 22.7 kg) increased from <$50 to $100 or higher during summer months (Wallace 1997), clammers tended to seek alternative areas that had been long-established harvesting sites for worms. Similarly, the 1980s saw a decline in worm landings in Maine (NMFS 2001) with a concomitant increase in price from $0.04 to $0.06 per worm to nearly $0.10 to $0.15 during summer months (B. Beal, pers. obs.). Wormers, like clammers, began to work outside of their traditionally harvested sites. The result was that both groups began to interact more frequently and, because of large disparities in the management of both species, this caused conflicts between the two groups of fishers.

Clams are comanaged by local stewards elected from each coastal community with a clamming habitat, who work together with officials from Maine's Department of Marine Resources (DMR). Commercial clam harvesting is licensed by both the town and state who together decide annually on the number of licenses to be sold in a particular town (Ellis & Waterman 1998). Today, most communities require clammers to participate in conservation programs prior to obtaining a license. These programs vary from assessing standing stocks or collecting water samples for testing levels of fecal contamination, to transplanting wild "seed" clams from upper to lower intertidal areas or enhancing wild stocks using hatchery-reared soft-shell clam juveniles. Although mandated, conservation programs give clammers a sense of responsibility for, and ownership of, the resource (B. Beal, pers. obs.).

Conversely, worms are not managed by local communities or the state of Maine because their mobility prevents adequate temporal predictions of standing stock (Creaser et al. 1983). Therefore, no management plan exists for blood worms or the other commercial bait worm in Maine, sand worms, except that harvesting must be done using hand-held tools and no Sunday digging is permitted. Wormers may dig on any flat along the coast, and their activities are not restricted by clam management programs. When local clam stewardship committees decide, for example, to institute a conservation closure for rotational purposes or to restock an area with wild or cultured juveniles, there is no legal mechanism to restrict the activities of bait worm diggers in these areas. Conflicts arise because clammers believe bloodworm harvesting kills or injures clams, especially juveniles that occupy the same infaunal depths as the worms. Similar conflicts have occurred from time to time in Maine. In fact, wormer-clammer interactions were discussed and debated by the Maine State Legislature as early as the late 1950s; however, no regulatory action was ever taken as it was decided to allow both groups to settle their own disputes (D. E. Wallace, pers. comm.).

Only one study has examined the effects of worm digging on *M. arenaria* populations in Maine. Ambrose et al. (1998) surveyed number and size of exposed soft-shell clams in freshly dug sediments created by bloodworm harvesters at an intertidal flat in Maine during Fall 1996. They found that approximately 6% of clams were transported to the sediment surface and that of these, 20% had at least one damaged valve. The fate of these clams was not assessed, nor did they examine the fate of animals that may have been excavated and buried within the dug areas. Ambrose et al. (1998) did assess mortality of clams experimentally exposed in several reburial trials and they found that animals placed in recently dug vs. unharvested sediments suffered greater predation risk.

In 1995, the marine resources committee of the southern Maine town of Brunswick enacted a conservation closure (no shellfishing for 1 y) on one of its intertidal flats because hatchery-reared soft-shell clam juveniles had been planted in the spring to enhance wild stocks. During that summer, wormers began commercially harvesting *G. dibranchiata* within the closed area. The local stewardship committee requested, and the commissioner of DMR approved, an emergency closure of the intertidal area to all types of commercial harvesting until such time that a study could be conducted to examine the effects of worming on the fate of small clams. It is rare that adaptive management strategies and experimental approaches are considered by fisheries managers (Botsford et al. 1997, Lenihan & Micheli 2000), but representatives from both fisheries agreed in principle with the approach and requested to be involved with the work.

From May 6 to August 1, 1996, we directly assessed the effects of harvesting commercial size soft-shell clams and bloodworms on the fate of both wild and cultured juveniles of *M. arenaria* at an intertidal flat in Casco Bay (southern Maine) in a small-scale, manipulative field experiment. Specifically, we examined growth and survival of small clams in: (1) unharvested plots either with or without protective, plastic netting; and (2) protected and unprotected plots dug by a professional clammer or wormer at various harvesting intensities. We recommend that bloodwormers not be excluded from areas of the intertidal closed to shellfishing with the objective of enhancing populations of juvenile clams unless a coastal community specifically undertakes direct measures to increase survival rates of the small clams.

MATERIALS AND METHODS

Study Site

The study was conducted from May 6 to August 1, 1996 in Brunswick, Maine near the mid intertidal zone at Maquoit Bay, a shallow (2–3 m at mean high water), semi-enclosed embayment

located in the northeastern corner of Casco Bay (43°51'42"N; 69°59'47"W). Sediments in Maquoit Bay vary in graphic mean size (±1 SE) from the upper (5.29 ± .015 Φ, $n = 2$) to the lower tidal zone (4.95 ± 0.15 Φ, $n = 2$). Salinity and temperature at the site ranged from 30 to 32 psu and 11°C to 19°C, respectively. Approximately 81 hectares of mudflats are exposed twice daily in the bay at mean low water (Heinig & Campbell 1992). An extensive eelgrass meadow (*Zostera marina* L.) existed from immediately below the mid-intertidal to the shallow subtidal and increased in biomass from early May through the summer (B. Beal, pers. obs.). Further features of the hydrography of Maquoit Bay are detailed in Heinig and Campbell (1992). All portions of the intertidal were closed to commercial and recreational shellfish and commercial bloodworm harvesting by the town of Brunswick's marine resources committee and the Maine DMR, respectively, during the study period, and this was effective in keeping both clammers and wormers from harvesting during the experimental period (B. Beal, pers. obs.).

Experimental Design

On May 6, a 1-hectare area near the mid-intertidal zone, approximately 100 m shoreward of the eelgrass meadow, was arbitrarily chosen as an experimental area. This muddy site contained quantities of commercial size *M. arenaria* (≥50.8 mm SL) and *G. dibranchiata* (see Creaser et al. 1983). To estimate initial density and size frequency of soft-shell clams and bloodworms, we took 10 haphazardly placed benthic cores (15 cm deep with an area of 0.0182 m^2) within the hectare and washed each sample through a 3.2-mm sieve. All clams and worms were enumerated and measured (clams – SL; blood worms – width at first setigerous segment; both to the nearest 0.1 mm using vernier calipers).

On the same date, we established 120 1-m^2 plots in a 6 × 20 matrix (2-m spacing between rows and columns) within the experimental area. Fifty hatchery-reared soft-shell clam juveniles (origin: Beals Island Regional Shellfish Hatchery [BIRSH], Beals, $\bar{x}$ SL ± 95% CI = 12.5 ± 0.39 mm, $n = 100$, range = 8.8–20.4 mm) were spread onto the surface of the mudflat in the 1/4-m^2 center of each plot. Small clams typically burrow into muddy sediments within 10 min (Beal 1994). We noted that most *M. arenaria* were not visible after the first 5 min and all had disappeared below the sediment surface after 30 min. Next, 100 of the 120 seeded plots were chosen randomly and covered (protected) with a piece of flexible netting (1.25 × 1.25 m; 6.4-mm aperture; InterNet Corporation, Minneapolis, MN). The remaining (20) seeded plots received no netting. Netting was secured around plots by spreading it over the plot and then forcing the perimeter into the mud to a depth of approximately 15 cm with our feet. A Styrofoam float (10 cm diameter × 4 cm wide) was affixed to the underside center of each piece of netting using a 10-cm-long wooden lath and galvanized nails. Floats enabled each net to rise from its middle above the surface of the flat surface during tidal inundation, permitting clams to filter without disruption (i.e., siphons did not contact the netting). Previous studies (Beal 1994) in muddy sediments indicated that nets without flotation tended to accumulate silt at rates that suffocated, rather than protected, clams beneath. The 20 unprotected plots, together with 20 of the 100 plots that received netting, were used to follow natural mortality and growth of cultured and wild clams in undisturbed sediments through time. These plots served as controls for the larger experiment (see below) that utilized the remaining 80 protected 1-m^2 plots.

On May 20, June 3, July 1, and August 1 (approximately 2, 4, 8, and 12 wk after the experiment was initiated), each of five protected and unprotected (control) plots was sampled ($n = 40$). We used our hands to dig sediments within the entire 1-m^2 to a depth of 15 cm where a hard clay layer existed below which clams on this flat do not burrow (Ambrose et al. 1998, B. Beal, pers. obs.). For the first three sampling dates, each plot was divided into four equal sections to better understand potential clam movement within the 1-m^2 plots. Sediment was sieved through a 3.2-mm mesh, and all cultured and wild clams were enumerated and measured (as above). Hatchery-reared clams are easily distinguished from wild clams due to a unique mark that develops on the shell once individuals are added to sediments (Beal et al. 1999). New shell growth of all living and dead animals (that grew before they died) appears as a white, easily measured band, compared to the darker area near the umbo that forms during crowded hatchery conditions. Other infauna within plots such as milky ribbon worms (*Cerebratulus lacteus* Leidy) and horseshoe crabs (*Limulus polyphemus* L.) were noted and/or counted and, when possible, measured (crabs: greatest carapace width [CW]) to establish size distributions. The five protected and unprotected plots sampled on August 1 served as undisturbed controls for the larger, 2^4 experiment (described below).

The remaining 80 plots protected with netting were assigned randomly to 16 harvesting treatments ($n = 5$) on May 6. A four-factor factorial design was developed after consulting with members of Brunswick's marine resources committee. The experiment was planned to better understand whether differences in survival and growth of wild and cultured juvenile clams could be attributed to the following factors, each with two levels: (1) type of harvesting (bloodworming vs. clamming); (2) rate, or intensity, of digging (plots dug once vs. twice); (3) date of digging (for plots dug once: 2 vs. 4 wk; for plots dug twice: 2 + 2 wk vs. 4 + 4 wk); and (4) protection (plots protected with netting for the duration of the experiment vs. plots with netting removed after final digging; Table 1). A professional clammer using a five-tined clam hoe (as described in Robinson & Rowell 1990) was hired and assigned to harvest (dig) 40 of the 80 plots. The remaining plots were similarly dug by a professional bloodwormer who used a five-tined hoe (as described in Creaser et al. 1983). Neither fisher was chosen by us, but from a pool of local harvesters by their own members.

Twenty of the 40 plots randomly assigned to the clammer were dug once and another 20 plots were dug once by the wormer. Plots were dug either 2 (May 20) or 4 wk (June 3) after the experiment was initiated. The remaining 40 plots (20 clammed and 20 wormed) were dug twice. One group was dug 2 wk after the start of the experiment (May 20) and then again after another 2 wk (June 3). The second group was dug 4 wk after the start of the experiment (June 3) and then again after another 4 wk (July 1).

Netting protected clams in each of the 80 plots until the date when commercial harvesting was scheduled (Table 1). Before digging within any plot, netting was completely removed. After harvesting plots assigned to the "dug once" treatment, one-half were covered again with the same piece of netting, which remained in place until the end of the experiment. The other one-half remained unprotected until the end of the experiment. For plots assigned to the "dug twice" treatment, netting was re-applied to each after the first harvest and it remained in place until the second harvesting. After the second digging, one-half of the plots were covered again with the same piece of netting, while the other one-half were left uncovered (Table 1). (During the study, fishers were given no information about any facet of the experimental design, and neither knew how many, if any, clams had been planted in each 1-m^2 plot.)

TABLE 1.

Experimental treatments initiated on May 6, 1996 and sampled on August 1, 1996 at Maquoit Bay, Brunswick, Maine. $n = 5$.

Treatment	Rate[1]	Date[2]	Protected[3]	Type of Harvesting[4]

18	DT	4 + 4	No	W

[1] CL = Control (i.e., not dug); DO = Dug Once; DT = Dug Twice.
[2] 2 = Harvested after 2 wk (May 20); 4 = harvested after 4 wk (June 3); 2 + 2 = harvested after 2 wk and then again 2 wk later (May 20 & June 3); 4 + 4 = harvested after 4 wk and then again 4 wk later (June 3 & July 1).
[3] Plastic mesh netting (6.4-mm aperture).
[4] C = Clammer; W = Wormer.

For plots dug once, fishers were instructed to begin digging 30 cm in from one side of the plot and to dig toward the opposite side (i.e., 70 cm away). This was done to ensure that all excavated sediment would remain within the 1-m^2 plot. Only sediment within the plot was excavated. For plots dug a second time, harvesters were directed to begin digging 30 cm in from the side of the plot where they had last finished digging and to dig toward the opposite side. Again, this harvesting pattern kept all dug sediments within the boundaries of each plot. In addition, each time plots were dug, harvesters were asked to remove all commercial size individuals they noticed of the species each normally would collect. These animals were enumerated and measured (as above). To monitor possible changes in abundance and size of commercial size clams and worms through time, on the last digging date (July 1), each fisher was asked to dig 10 haphazardly chosen 1-m^2 plots outside and adjacent to the 6 × 20 matrix. All commercial worms or clams within these plots were collected, enumerated, and measured (as above).

During the period from July 28 through August 1, each of the 80 harvested plots was sampled as described above, and sediments from each plot were washed through sieves with 3.2-mm apertures. Cultured and wild clams found within each plot were counted and relative growth rate was calculated for each live clam of hatchery origin using the following formula:

$$RG = ([\text{final length} - \text{initial length}]/\text{initial length}) \times 100\%.$$

A random subset of all wild clams from each of the 16 treatments was measured to the nearest 0.1 mm using vernier calipers to estimate final size (SL) frequency.

Statistical Analyses

The design for the 2^4 experiment was a completely randomized one with all four factors fixed (see below). This design yields maximum degrees of freedom to estimate experimental error, and assumes that the area over which the experiment is conducted is homogeneous with respect to biotic and abiotic variables (Steel & Torrie 1980).

Analysis of variance (ANOVA) was used to test all statistical hypotheses. Prior to any analysis, the variance homogeneity and normality assumptions of ANOVA were tested using Cochran's and Shipiro-Wilk's tests, respectively. When significant heteroscedasticity of variances or departure from normality occurred, a transformation was applied to the raw data, and the transformed data were re-tested for variance homogeneity. A source of variation (hypothesis) was considered significant if it was associated with a probability ($P < 0.05$).

A two-way, model I ANOVA was performed on data (arcsine-transformed mean percentage of clam survival, final mean length of hatchery-reared and wild clams, square root-transformed mean number of wild clams) from the control plots where sampling date (a = 4) and netting (b = 2) were the independent variables. A nested, model I ANOVA was performed on similar data from the 2^4 experiment using following linear model:

$$Y_{ijklm} = \mu + A_i + B_j + AB_{ij} + C_k + AC_{ik} + BC_{jk} + ABC_{ijk} + D(C)_{l(k)} + AD(C)_{il(k)} + BD(C)_{jl(k)} + ABD(C)_{ijl(k)} + \epsilon_{m(ijkl)}$$

where: Y_{ijklm} = dependent variable (arcsine-transformed mean percent survival, mean relative growth, square root-transformed mean number of wild clams); μ = overall mean; A_i = type of harvesting (clamming vs. worming); B_j = protection (netting vs. no netting); C_k = rate, or intensity, of harvesting (plots dug once vs. twice); $D(C)_{l(k)}$ = date of harvesting (2 vs. 4 wk; 2 + 2 wk vs. 4 + 4 wk) nested within rate of harvesting; $\epsilon_{m(ijkl)}$ = experimental error—a measure of variation that exists among observations on experimental units treated alike.

Date of harvesting (D_l) is nested within rate of harvesting (C_k) because both rates (dug once vs. dug twice) did not occur on each date when plots were dug (2 vs. 4 wk). That is, plots dug once were only dug after 2 and 4 wk. Plots dug twice were dug on a 2 + 2 wk or 4 + 4 wk basis.

Means, presented graphically or in the text, represent untransformed data ± 95% confidence intervals.

RESULTS

Initial Sampling: May 6, 1996

A mean density of 229 ± 152 individuals/m^2 of *M. arenaria* (SL size range = 5–22 mm) and 0.95 ± 0.55 individuals/m^2 of *G. dibranchiata* (range of greatest width = 3.9–7.9 mm) was found in the 10 benthic cores. The clam, *Macoma balthica* (L.), was the most numerous other large infaunal species within the cores (427.8 ± 395 individuals/m^2) and ranged in size (SL) from 4.2 to 17.4 mm. Although we did find evidence of the nemertean *Cerebratulus lacteus* in most cores, the sieving process damaged the worms too severely and, as a result, we were unable to enumerate or measure individuals.

Control Plots: Hatchery-Reared Clams

Survival of cultured soft-shell clams in both protected and unprotected plots decreased rapidly during the first month of the experiment (Fig. 1). ANOVA indicated that both main factors

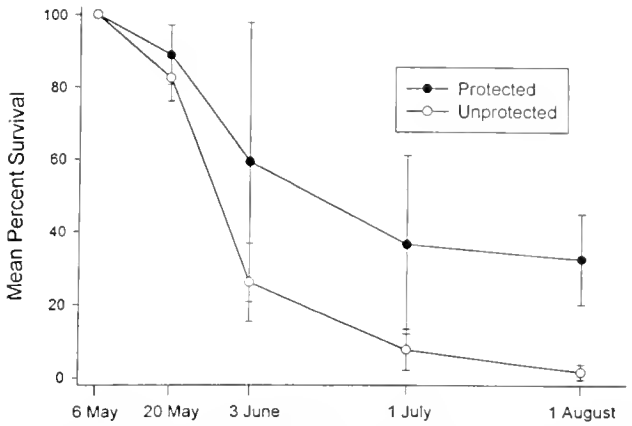

Figure 1. Mean percentage of survival (±95% confidence interval) of hatchery-reared juveniles of *M. arenaria* in 1-m² unharvested (control) plots at Maquoit Bay (Brunswick, ME) from May 6 to August 1, 1996. ANOVA revealed significant clam mortality through time ($P < 0.0001$), and SNK test showed that average survival did not change from July 1 to August 1. Mean survival was consistently ($P < 0.0001$) higher in protected plots. $n = 5$.

(sampling date and level of protection) were highly significant ($P < 0.0001$) and that the differences observed between protected and unprotected plots were consistent through time ($F = 2.14$, df = 3, 32, $P = 0.1140$). An *a posteriori* Student-Newman-Keuls (SNK) test indicated that mean percentage of survival did not decrease significantly after July 1. On August 1, mean clam survival in the plots protected with netting was nearly 20 times greater than survival in plots without protective netting ($\bar{x}_{net} = 32.4 \pm 12.45\%$ vs. $\bar{x}_{no\ net} = 1.6 \pm 2.08\%$; $n = 5$).

The majority of observed mortality (Table 2a) likely was due to processes that kill clams without physically damaging the valves (starvation, disease, and predation by organisms that leave no discernible shell damage) or from predators that crush valves into small (<3.2 mm) fragments. Nearly 90% of clams in the unprotected plots were missing by August 1 compared to 15% in the protected plots (Table 2a). Some missing clams may have been alive, but either had emigrated or been moved from the 1-m² plots by unsuccessful predators. Clam movement, assessed by comparing the number of live animals sampled from the center 1/4-m² areas where they were planted vs. three similar-sized areas within each plot, appeared to increase through time. For example, on the first sampling date (May 20), 98.1% (202/206) and 93.7% (208/222) of live clams were found within the seeded center area of the unprotected and protected plots, respectively. Approximately 8 wk after the experiment was initiated (July 1), 68.4% (13/19) and 75.8% (69/91) of those in unprotected and protected plots, respectively, were found in the area they had been planted.

Only a few clams were found dead with crushed or chipped valves; however, a total of nine *L. polyphemus* was found during the first three sampling dates, and only in plots with protective netting (CW on May 20: 12 and 38.2 mm; June 3: 70.0 and 83.2 mm; July 1: 27.2, 43.8, 46.2, 50.2, and 64.2 mm). The two *L. polyphemus* discovered on June 3 were in a single plot. Only two of 50 hatchery-reared clams were recovered alive from that plot, whereas the other four protected plots sampled on June 3 contained 34, 37, 37, and 38 of 50 clams initially planted. On the final sampling date (August 1), one horseshoe crab was found in one of the five protected plots (23.9 mm) and one occurred in four of five of the unprotected plots (11.1, 32.3, 55.8, and 58.0 mm). A minimum of two *C. lacteus* (approximately 70 mm TL) was found primarily in protected plots on each sampling date. Only one *C. lacteus* (approximately 90 mm TL) was sampled from the unprotected plots (June 3); however, smaller worms (approximately <40 mm) were also present in most of plots on each date. These animals tended to fragment easily during the sieving process, making accurate estimates of their size and density not possible.

Clam growth was unaffected by the presence of netting ($F = 1.83$, df = 1, 28, $P = 0.1867$). Although ANOVA detected a significant increase in mean SL through time ($F = 15.35$, df = 3,

TABLE 2.

a) Mean percentage (±95% confidence interval) of hatchery-reared soft-shell clam juveniles that were alive (A), dead, with undamaged valves (DU), dead, with crushed or chipped valves (DC), or missing (M) from 1-m² plots on four sampling dates. b) Mean number (±95% confidence interval) of wild individuals of the soft-shell clam from the same plots. Fifty hatchery-reared individuals (mean SL = 12.5 mm) were added to each of $n = 5$ protected (plastic mesh netting; 6.4-mm aperture) or unprotected plots on May 6, 1996. $n = 40$.

28, $P < 0.001$), clams grew, on average, only 4.8 ± 1.2 mm (n = 7 plots) over the nearly 3-mo test, attaining a final mean SL on August 1 of 17.3 ± 1.2 mm. The majority of growth occurred during the final month of the experiment (Fig. 2a).

Control Plots: Wild Clams

The mean number of wild clams varied widely through time (Fig. 3). Both main (sampling date and protection) factors and the interaction term were highly significant ($P < 0.001$). Single-factor ANOVAs for each level of protection were performed to facilitate interpretation of clam losses. Clams in both protected and unprotected treatments suffered significant losses through time ($P < 0.01$; Table 2b). SNK tests revealed that in unprotected plots, a significant number of clams disappeared between the first and second sampling date clams, but no significant additional losses occurred after July 1. In plots protected with netting, no significant differences in clam numbers were detected between May 20 and June 3. Significant losses occurred between June 3 and July 1, but

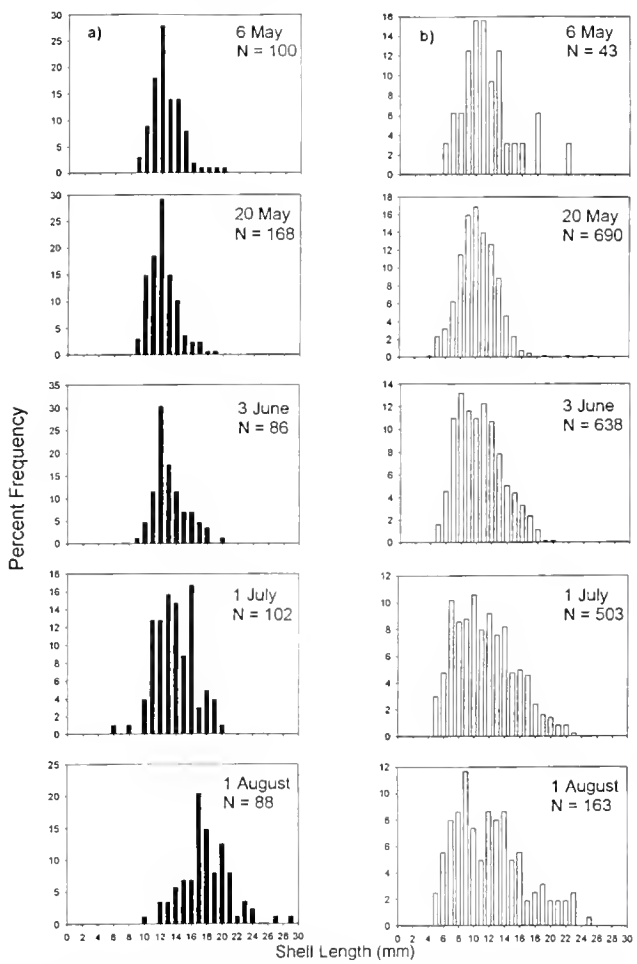

Figure 2. Size frequency distribution of cultured (a) and wild (b) soft-shell clams within 1-m^2 control plots (n = 5) at Maquoit Bay (Brunswick, ME) on each sampling date (except that wild clams on May 6 were sampled from a total of 10 benthic cores [Area = 0.0182 m^2]). Numbers (N) associated with each graph represent total number of clams within plots or cores (except on August 1, where N for the wild clams represents a random sample of taken from 4,386 individuals within 90 plots). ANOVA demonstrated significant increases in mean SL through time for cultured, but not wild, clams.

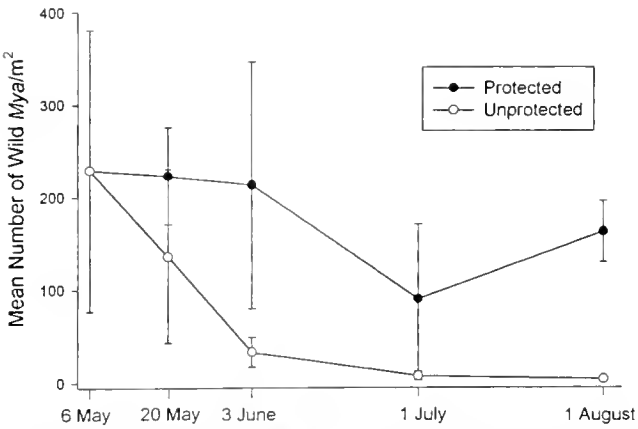

Figure 3. Mean number (±95% confidence interval) of wild individuals of *M. arenaria* within 1-m^2 control plots at Maquoit Bay (Brunswick, ME) on each sampling date (May 20 to August 1, 1996). Initial density was determined from 10 benthic cores taken haphazardly within the experimental area on May 6, 1996. ANOVA performed on data from the 1-m^2 plots indicated both main factors (protection and time) and the interaction of these factors were highly significant ($P < 0.001$). n = 5.

then average numbers appeared to increase to pre-July levels. This variability in mean number may be related to the fact that two horseshoe crabs were found within a single protected plot sampled on June 3 (see above). That replicate contained 104 wild clams, whereas 393, 182, 179, and 209 were sampled from the other four protected plots. In addition, a group of small clams (<5 mm SL) appeared on the final sampling date in the protected plots that may have been too small to be sampled efficiently earlier. These were not 0-y class individuals, as each contained a disturbance ring (winter check) on both valves at 1 to 2 mm SL. By August 1, approximately 40 times the number of wild clams was found in protected plots (162.4 ± 32.85 individuals/m^2) compared with unprotected plots (3.80 ± 2.89 individuals/m^2).

No significant difference in mean SL of wild clams was detected between protected and unprotected plots ($F = 0.67$, df = 1, 32, $P = 0.4191$) nor was there any significant change in mean SL through time ($F = 2.04$, df = 3, 32, $P = 0.1280$; Fig. 2b). The apparent lack of growth also may be related to the appearance of the small clams in samples on August 1.

Movement of wild clams within the 1-m^2 plots was measured indirectly. Since each plot was subdivided into four equal sampling areas for each of the first three sampling dates, we asked whether the distribution of clams observed in the four areas varied through time. We assumed that clam movement occurred if the distribution changed through time. Distribution did not vary significantly in protected ($G = 9.27$, df = 6, $P = 0.1587$) or unprotected ($G = 8.66$, df = 6, $P = 0.1943$) plots.

2^4 Experiment

Hatchery-Reared Clams

Of the 11 sources of variation (hypotheses), the most important (i.e., explaining the largest percent of total variation) associated with percentage of clam survival was that due to protection (meshed vs. unmeshed plots; 51.5%), but this effect depended on the rate plots were dug ($P < 0.0001$; Table 3). Mean survival was higher in protected treatments dug once vs. twice (23.3 ± 3.3% vs.

TABLE 3.

Analysis of variance on the arcsine-transformed percentage survival of hatchery-reared soft-shell clam juveniles within each dug plot after 12 wk (August 1, 1996). $n = 5$.

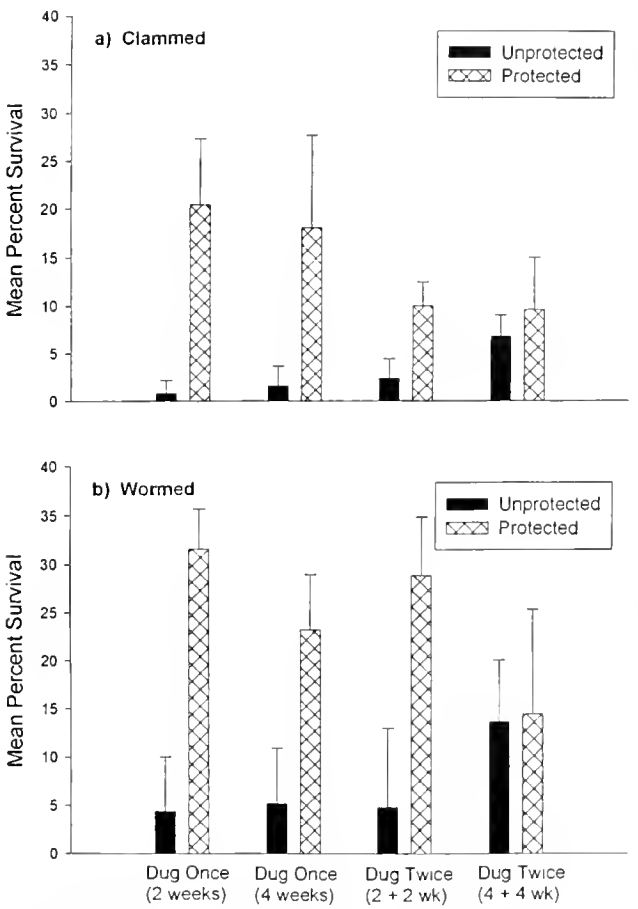

Figure 4. Mean percentage of survival (±95% confidence interval) of cultured soft-shell clams in the eight clammed and eight wormed treatments (Table 1) at Maquoit Bay (Brunswick, ME) on August 1, 1996. Fifty cultured clams (mean SL = 12.5 mm) were placed in the 1/4-m^2 center of $n = 5$ 1-m^2 plots on May 6, 1996. Data represent the percentage of those clams sampled in the entire 1-m^2 plot. ANOVA was used to compare survival between type of fisher, level of protection, intensity of digging, and length of time when digging occurred after the experiment was initiated (see Table 3). $n = 5$.

15.7 ± 4.44%, $n = 20$). This trend was not observed in unprotected treatments where 3.0 ± 1.70% survived in plots dug once vs. 6.9 ± 2.74% in those dug twice. The type of harvesting method, independent of other main or interactive effects, was also highly significant ($P < 0.0001$; Table 3; Fig. 4). Mean survival in clammed treatments was nearly one-half that observed in wormed plots (8.7 ± 2.51% vs.15.75 ± 3.69%, $n = 40$). The only other significant source of variation was that due to Date × Protection (Rate). Decomposing this source of variation into its two orthogonal components revealed that for plots dug twice, the effect of protecting clams with netting, was more pronounced when they were dug on a 2 + 2 wk schedule than when dug on a 4 + 4 wk schedule (Table 3; Fig. 4). This result is not too surprising because unprotected plots dug twice on a 4 + 4 wk basis were actually protected with netting a month longer than animals in the 2 + 2 wk treatments. It also reflects the temporal difference in clam loss observed in the controls between June and July vs. July and August (Table 2a).

TABLE 4.

Analysis of variance on the untransformed relative growth data for living hatchery-reared soft-shell clams within each dug plot after 12 wk (August 1, 1996). Not all plots contained live clams at the end of the experiment, making the data unbalanced. Type III sums of squares were used in all hypothesis tests (Shaw & Mitchell-Olds 1993).

To determine whether digging and type of digging generally had an effect on clam survival compared to the undisturbed controls, we conducted two additional, single-factor ANOVAs. The first analysis tested whether mean percentage of survival differed between unprotected controls ($\bar{x}$ = 1.6 ± 2.08%, n = 5) and unprotected, but dug, plots from the larger experiment ($\bar{x}_{clammed}$ = 2.9 ± 1.31%, n = 20; $\bar{x}_{wormed}$ = 7.0 ± 2.92, n = 20). The second analysis tested whether mean percentage of survival differed between protected controls ($\bar{x}$ = 32.4 ± 12.45%, n = 5) and protected, but dug, plots from the larger experiment ($\bar{x}_{clammed}$ ± 3.24%, n = 20; $\bar{x}_{wormed}$ = 24.5 ± 4.00, n = 20). Because these tests were not independent of those conducted previously, we conservatively lowered the type I error rate for each according to Winer et al. (1991). Data in both tests was used twice; therefore, we let n = 2 in the following equation: $\alpha_{adjusted} = 1 - (0.95)^{1/n}$. This yielded an adjusted type I error rate, α = 0.0253. No difference in mean clam survival was detected between the unprotected controls and dug plots (F = 3.64, df = 2, 42, P = 0.0349), but a significant effect due to fisher type was observed among protected treatments (F = 12.21, df = 2, 42, $P < 0.0001$). An *a posteriori* SNK test showed that mean survival in controls and plots dug by the wormer was similar and that both were significantly higher than mean survival of clams in plots dug by the clammer.

Mean relative growth rates were unaffected by type of harvesting, but they did vary interactively with level of protection and harvesting rate (Table 4; Fig. 5). Clams grew approximately 10% slower in unprotected treatments dug once vs. twice (20.97 ± 10.12%, n = 11 vs. 30.26 ± 9.85%, n = 13). Conversely, clams grew nearly 6% faster in protected treatments dug once vs. twice (37.29 ± 3.66%, n = 20 vs. 31.38 ± 6.06%, n = 18). As with the survival analyses, we asked whether growth rates of animals in the controls differed from those in the larger, 2^4 experiment, and we divided this into separate analyses for unprotected and protected treatments. We used the conservative α = 0.0253, as above. Only two of five unprotected control plots contained live clams (RG = 18.43 ± 78.95%) vs. 10 of 20 unprotected clammed (RG = 24.92 ± 14.61%) and 14 of 20 unprotected wormed (RG = 26.77 ± 7.51%) plots. No significant difference in growth rate due to type of fisher was noted (F = 0.24, df = 2, 23, P = 0.7890), but the power of this test was very low (< 0.3). Similarly, for the protected plots, no effect due to type of fisher on relative growth was detected in protected plots ($\bar{x}_{control}$ = 42.38 ± 10.06%, n = 5; $\bar{x}_{clammed}$ = 33.47 ± 5.98%, n = 18; $\bar{x}_{wormed}$ = 35.40 ± 4.18%, n = 20; F = 1.47, df = 2, 40, P = 0.2426), but again, the power to detect differences was low (0.6).

Wild Clams

Wild clams behaved similarly to the hatchery-reared animals (Table 5). Approximately 55% of the total variation in mean number of live individuals was explained by the presence or absence of netting; however, this effect depended on both type (P = 0.0007) and rate of harvesting (P = 0.0001). Protecting clams with netting resulted in more than twice the number of wild clams in plots harvested by the wormer compared with those harvested by the clammer. For example, mean difference in number of wild clams between protected and unprotected treatments was 79.2 ± 21.3 individuals/m^2 in plots harvested by the wormer compared with 35.1 ± 11.69 individuals/m^2 in clammed plots (n = 20; Fig. 6). Application of plastic netting to plots resulted in 2.5 times more individuals from treatments dug once vs. twice. The mean difference in numbers of wild clams between netted and unnetted plots dug once vs. twice was 81.9 ± 22.22 vs. 32.4 ± 13.35 individuals/m^2 (n = 20). In addition, the interaction of type and date of harvesting nested within harvesting rate was significant (P = 0.0389; Table 5). As with hatchery-reared clams, effects due to protecting wild clams with netting were more pronounced (both for clammed and wormed plots – Fig. 6) for the shorter (2 + 2 wk) compared to the longer (4 + 4 wk) harvesting intervals.

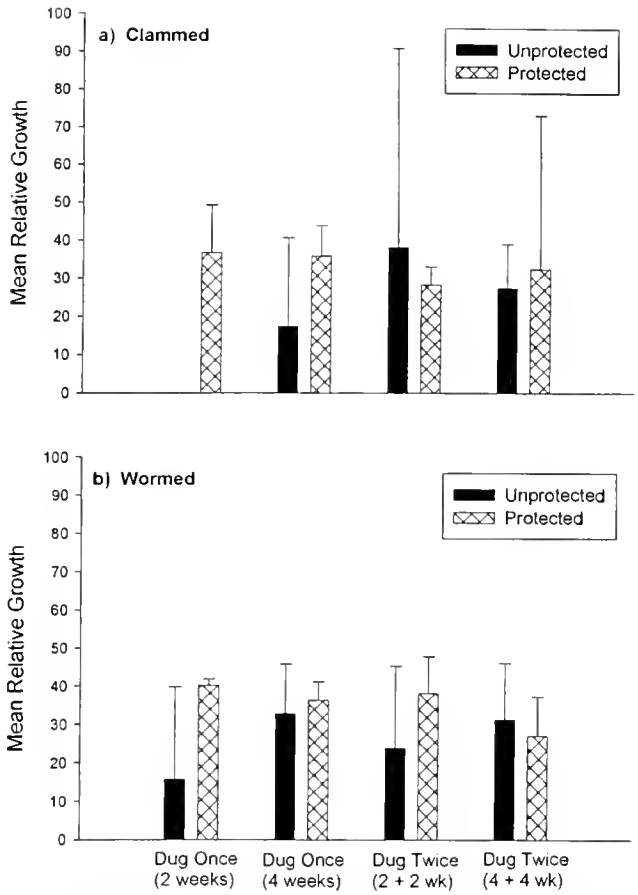

Figure 5. Mean relative growth (±95% confidence interval) of cultured soft-shell clams in the eight clammed and eight wormed treatments (Table 1) at Maquoit Bay (Brunswick, ME) on August 1, 1996. ANOVA was used to compare relative growth between type of fisher, level of protection, intensity of digging, and length of time when digging occurred after the experiment was initiated (see Table 4). n = 5.

We tested whether an overall effect due to digging and digging type existed by comparing, as above, mean number of clams in unprotected and protected controls, separately, to plots treated similarly in the larger, 2^4 experiment. No significant difference ($P > 0.0253$) in mean number was observed in unprotected treatments ($\bar{x}_{control}$ = 3.8 ± 2.39 [n = 5] vs. $\bar{x}_{clammed}$ = 14.1 ± 4.92 [n = 20] vs. $\bar{x}_{wormed}$ = 17.7 ± 7.05 [n = 20]; P = 0.0258). Significantly more wild clams were found in protected controls vs. protected but dug treatments ($\bar{x}_{control}$ = 162.4 ± 32.50 [n = 5] vs. $\bar{x}_{clammed}$ = 49.2 ± 11.74 [n = 20] vs. $\bar{x}_{wormed}$ = 96.9 ± 21.37 [n = 20]; $P < 0.0001$). An SNK test indicated significant differences between all three means.

Commercial Clams and Worms Harvested from 1-m^2 Plots During the Experiment

Experimental plots were dug on three occasions (May 20 = 40; June 3 = 60; July 1 = 20). We asked whether the square root-

TABLE 5.

Analysis of variance on the square root-transformed number of wild soft-shell clams alive within each dug plot after 12 wk (August 1, 1996). $n = 5$.

Source of Variation	df	SS	MS	F	$Pr > F$

Total	79	717.49			

transformed mean number and untransformed mean size of animals harvested from each plot varied among sampling dates (Fig. 7). ANOVA detected no significant differences either in mean number ($F = 0.78$, df = 2, 57, $P = 0.4630$) or mean SL ($F = 1.63$, df = 2, 28, $P = 0.2133$) of clams through time. Interestingly, mean number of clams/m^2 adjacent to the experimental site on July 1 (0.9 ± 0.41, $n = 10$) was nearly identical to numbers harvested initially from experimental plots on May 20 (0.95 ± 0.58, $n = 20$). Mean SL of commercial clams within all plots was 64.5 ± 2.16 mm ($n = 39$). No differences were detected in mean number or size of worms per plot from May 20 to July 1 ($F_{number} = 0.88$, df = 2, 57, $P = 0.4205$; $F_{size} = 0.06$, df = 2,34, $P = 0.9385$; Fig. 7). Mean number of bloodworms per 1-m^2 varied little through time. On May 20, 0.95 ± 0.44 individuals ($n = 20$) were harvested from the plots, whereas 1.2 ± 0.74 animals ($n = 10$) were harvested in plots outside the experimental site on July 1. Mean size (greatest diameter) of all worms collected was 5.4 ± 0.32 mm ($n = 37$).

Other Large Infauna Occurring in the Plots at the End of the 2^4 Experiment

The baltic clam, *Macoma balthica*, was the most numerous large infauna within the plots; however, these animals were neither enumerated nor measured. Although horseshoe crabs were found in 50% of the control plots on August 1 (see above), only 15 of the 80 dug plots (18.75%) sampled on that date contained *L. polyphemus*. Horseshoe crabs were found in six of the clammed and nine of the wormed plots. Mean CW of these 24 individuals was 45.5 ± 3.9 mm (range = 10.5–79.8 mm). *C. lacteus* was also found in most protected plots, but again, worms generally were small (approximately < 40 mm TL) and were not enumerated because they tended to fragment easily.

DISCUSSION

This work was intended to investigate the short-term effects of clam and bloodworm harvesting within the soft bottom intertidal on the fate of cultured and wild individuals of the soft-shell clam. Had we not included adequate controls to monitor changes in mean

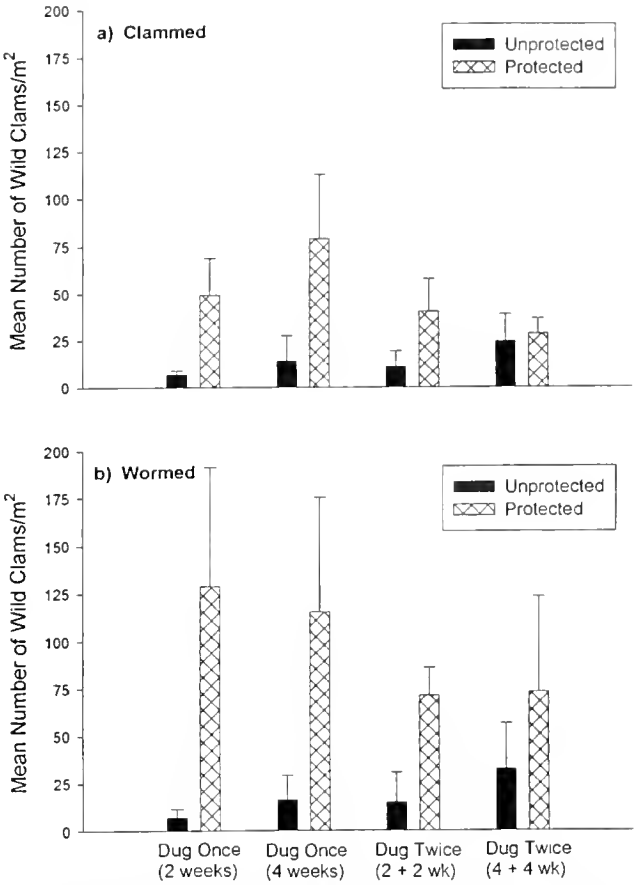

Figure 6. Mean number of wild soft-shell clams (±95% confidence interval) in the eight clammed and eight wormed treatments (Table 1) at Maquoit Bay (Brunswick, ME) on August 1, 1996. Initial density at the beginning of the experiment on May 6, 1996 was 229 ± 152 individuals/m^2. ANOVA was used to compare mean number between type of fisher, level of protection, intensity of digging, and length of time when digging occurred after the experiment was initiated (see Table 5). $n = 5$.

clam survival through time, we likely would have reached a different conclusion about our results. The controls demonstrated clearly that natural losses due to processes that removed clams from the plots (predation and/or emigration) were more important than any effect observed either due to clam or bloodworm harvesting. Each comparison of means between unprotected controls and unprotected, but dug, treatments in the 2^4 experiment was not significant. Had our ability to detect differences between means not been reduced by the necessity to adjust the type I error rate of these tests, we would have concluded that survival of cultured clams and final mean number of wild clams was actually higher in the dug vs. control plots. That is, there might be some benefit to turning over the sediments. Only when we examined the fate of clams protected by netting could we discern any effects due to type of harvesting. The ANOVAs demonstrated that at least for hatchery-reared clams, effects due to worming on mean growth and survival were negligible compared to controls. Clamming, on the other hand, contributed an additional 15% loss of juvenile clams compared to controls. We did detect a negative effect due to bloodworm harvesting on numbers of wild clams in protected plots, but the effect was not as severe as that from clamming. Approximately 40% and 70% fewer wild clams were found in plots harvested by

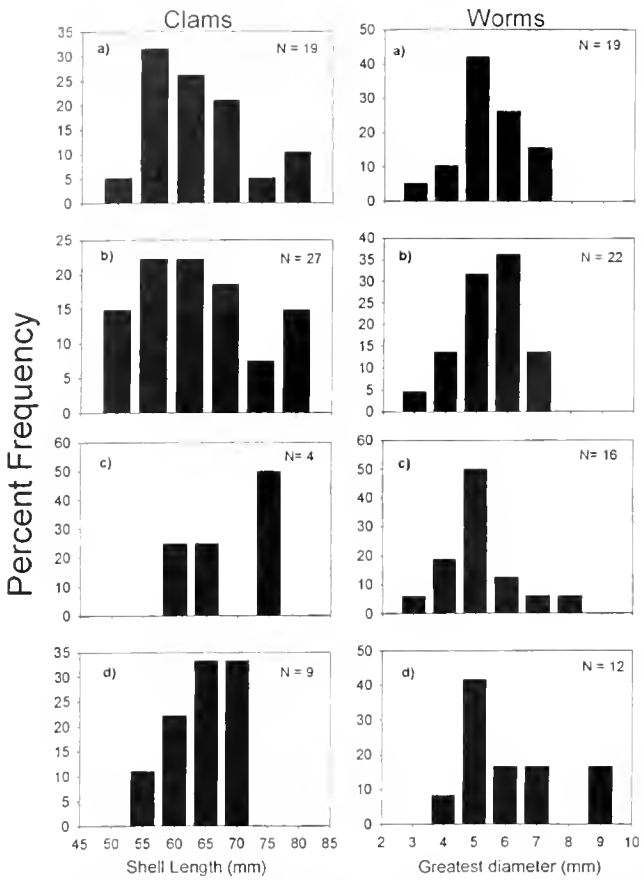

Figure 7. Size frequency distribution of commercial size soft-shell clams and blood worms collected by the clammer and wormer, respectively, from 1-m² plots from the 2^4 experiment at Maquoit Bay (Brunswick, ME) in 1996. a) May 20 (n = 20); b) June 3 (n = 30); c) July 1 (n = 10). Distributions represented in d were taken on July 1 (n = 10) outside and adjacent to the 6 × 20 experimental matrix. Mean SL of *Mya* (64.5 ± 2.16 mm; n = 39) and mean width of *Glycera* (5.4 ± 0.32 mm; n = 37) did not change through time nor did density ($P > 0.05$).

the bloodwormer and clammer, respectively, compared to protected controls.

Results from the 2^4 experiment alone suggest that clamming had the greater negative impact on clam survival than bloodworming (Tables 3 and 5; Figs. 4 and 6); however, we did not examine the mechanism. Observed differences in survival of cultured clams and numbers of wild clams between clammed and wormed treatments may be related to the depth that harvesters must dig to find commercial size animals. For example, commercial size *M. arenaria* burrow ≥15 cm (Zwarts & Wanink 1989) compared to 5 to 10 cm for *Glycera* (Creaser et al. 1983). The tools each type of fisher uses also reflects these life history traits. That is, the tines of clam hoes are significantly longer than tines on hoes used by wormers; therefore, the volume of sediment excavated when searching for clams vs. worms is greater (B. Beal, pers. obs.). Since clam survival is inversely proportional to burial depth (Glude 1954), we infer that clam harvesting adds synergistically to the already large losses of small clams due to natural causes.

Hatchery-reared clams used in this study were in the range of sizes of relatively mobile individuals (Baptist 1955, Beal, 1994). One question might be that since no barriers or enclosure walls (*sensu* Peterson & Beal 1989) were used to restrict clam movements, how is it possible to distinguish the difference between emigration from unprotected plots and clam mortality? We seeded small, cultured clams into the middle 1/4-m² of each 1-m² plot, while the remaining area around it was used as a buffer zone for emigrants. We assume that were emigration important in explaining the relatively high percentage of clams missing from the unprotected controls (Table 2a), most movement from the plots would have occurred within the first 2 wk (May 6 to 20) after plots were seeded. On the first sampling date (May 20), 14% of cultured clams were missing within the five unprotected control plots. Of the remaining 83% of living hatchery-reared clams, 98% were sampled from the middle 1/4-m² of each plot. In addition, although clam movement in protected controls was restricted to the 1-m² area, we found 94% of live animals to be within the seeded middle area on the first sampling date. These data suggest that if clams did emigrate from the 1-m² plots, the rate was very low. In addition, comparable data showed that wild clams had moved very little.

The severe losses of hatchery-reared clams in the controls (protected = 68%; unprotected = 98%) mirrored large losses of small wild clams in the same plots (protected = 27%; unprotected = 97%). Numbers of wild individuals in protected controls appeared to increase from July 1 to August 1, but this was likely due to a combination of two events. The first was a group of small clams (<5 mm) that apparently had grown into the size range sampled more efficiently by the 3.2-mm mesh. The second was predation. It is reasonable to conclude that the majority of clams lost from control plots was due to intense predation. Large predators such as horseshoe crabs were noted on each sampling date. The best evidence that predation occurred and was an important factor in explaining the high percentage of clam losses came from a single protected plot on June 3. In four of five protected plots, the mean number of live hatchery-reared clams recovered out of 50 planted was 36.5, or 73%, and the mean number of wild clams was 241. Two juveniles of *L. polyphemus* were found in the fifth plot that contained only 2 of 50 (4%) living, cultured clams (the rest were missing) and 104 (or 57% fewer) wild clams.

Another line of evidence that predation was important was the number of nemertean worms observed in the control samples, as well as from the larger experiment. Rowell and Woo (1990) provided the first experimental evidence from both field and laboratory trials that *C. lacteus* consumes individuals of *M. arenaria*. These worms leave no apparent damage to the valves such as crushing, chipping, or drilled holes commonly associated with crustaceans and naticid gastropods, respectively. *C. lacteus* gains entry to prey such as *M. arenaria* by wriggling its whole body or proboscis through either the siphons or the anterior pedal hole in the mantle (Kalin 1984). Since cytolytic and neurotoxic proteins are localized in the integumentary tissues of the body wall and proboscis of this predator (Kem 1985, Barnham et al. 1997), it is able to kill its prey without damage to the valves. In this study, numbers of dead, undamaged valves of both hatchery-reared and wild clams in control plots were high (Table 2a and b) and may have been related to nemertean worm predation.

Stress due to mishandling cultured clams and/or disease of wild or cultured individuals are alternative hypotheses for explaining the high proportion of dead, undamaged valves; however, these seem unlikely. Clams (8–20 mm SL) obtained from BIRSH were produced in 1995 and held over the winter (see B. Beal et al. 1995). Survival varied between 95% and 98% (B. Beal, pers. obs.). Hatchery-reared individuals within this range of sizes also were used in a manipulative field experiment initiated in April 1996 on

an intertidal mud flat in eastern Maine (Jonesport; latitude 44°37'N, 67°34'W). In that study clams were planted at densities of 666, 1,332, and 2,664/m^2 in protected and unprotected experimental units at each of three distinct tidal heights. Units (n = 180) sampled on June 5 and August 3, 1996 contained 94.2% and 86.4% live clams, respectively (Beal et al. 2001). No *C. lacteus* or *L. polyphemus* occured on this flat (B. Beal, pers. obs.). Since clams used in both studies were of the same origin and were handled similarly prior to experimental manipulation, it is unlikely that stress due to handling was a significant factor in soft-shell clam mortality in the present study. In addition, although not specifically tested here, since 1992, cultured soft-shell clam juveniles from BIRSH have been routinely (annually) examined histologically for gonadal (B. Barber, University of Maine, Orono, pers. comm.) and hemocytic (S. McLaughlin, NOAA, Cooperative Oxford Laboratory, Oxford, MD, pers. comm.) neoplasia prior to shipping seed out of state. No prevalence of either type of neoplastic cell has been reported.

The level of protection was the most important source of variation in each of the three ANOVAs associated with the 2^4 experiment (Tables 3–5), but in each case, the Protect × Rate interaction term was significant. Wild and cultured clams were found in greater abundance within protected vs. unprotected plots regardless of whether plots were dug once or twice; however, the effect due to netting was greater when plots were dug once vs. twice. This fact, and the failure of ANOVA to detect an effect of rate of digging alone, was partially a result of the experimental design, as unprotected plots dug twice were covered with netting during the time between harvests. In the case of treatments 15 through 18 (4 + 4 wk; Table 1), there is little difference in means between protected and unprotected treatments (Figs. 4 and 6). In protected plots, cultured clam survival was 8% higher, and 43% more wild clams were found in plots dug once vs. twice. When we reanalyzed data from Tables 3 and 5 by ignoring all information from unprotected plots, these percentages were highly significant ($F_{survival}$ = 19.44, df = 1, 32, $P < 0.0001$; F_{number} = 17.50, df = 1, 32, $P < 0.0001$) and suggested that repeated digging of flats results in significant additional clam losses. The presence of netting enhanced growth of cultured clams by nearly 17% in treatments dug once, but this same effect was not observed in treatments dug twice. Again, this may be related to the extra time that unprotected plots were covered with netting. Glock and Chew (1979) found similar growth enhancement in Japanese littlenecks, *Venerupis japonica* (DeShayes), at an intertidal flat in Washington state; however, previous field trials in eastern Maine using cultured seed of *M. arenaria* (Beal 1993) yielded no differences in clam growth between netted and unnetted experimental units.

Except for Ambrose et al. (1998), previous studies on impacts of digging soft-bottom sediments on the fate of soft-shell clams have focused directly or indirectly on effects caused by clammers (Glude 1954, Medcof & MacPhail 1964, Emerson et al. 1990, Robinson & Rowell 1990). Depending on sediment type, harvesting can be 60% to 85% efficient and can also damage or kill animals missed or are left behind intentionally. Unharvested clams may be exposed on the sediment, increasing their risk to predation by birds, fish, and crustaceans, or may be buried at depths that cause them to suffocate. Glude (1954) conducted field experiments in Maine to assess the effects of burial on soft-shell clams (9.5–50.8 mm SL) in muddy sediments. With siphons oriented in three positions (upright, horizontal, and upside down), clams were buried at depths from 2.5 to 23 cm. Survival was related directly to clam size, burial position, and depth. The range of estimates of direct mortality of clams from hoes or forks varies between 2% and 50% (Dow et al. 1954, Medcof & MacPhail 1964, Hruby 1982, Robinson & Rowell 1990). Both Dow et al. (1954) and Robinson and Rowell (1990) determined that breakage (chipped or cracked valves) of clams (13–57 mm) by hoes in commercially productive areas averaged between 17.6% and 19.6%. These means increased with increasing clam density and sediment compaction. Dow et al. (1954) showed that breakage increases with increasing clam size, but Robinson and Rowell (1990) found no clear trend between mortality rate and clam size. Robinson and Rowell (1990) concluded that incidental mortality of clams due to harvesting could significantly affect clam stocks by decreasing yields.

The work by Ambrose et al. (1998) represents the first examination of bait worm digging on soft-shell clam populations. They concluded that commercial harvesting of *G. dibranchiata* has negative effects on clam abundance and that these effects should be considered in state and local clam management programs. Experimental evidence presented here supports their recommendation. We conclude that clamming and worming both contribute negatively to the loss of small soft-shell clams. However, these losses are considered unimportant during the summer months when natural mortality is high due to predation and other sources, especially in areas where netting is not applied to intertidal flats to protect clams from predators or to encourage recruitment of wild seed clams (Beal 1993). Our study and that of Ambrose et al. (1998) was a short-term trial conducted at a single-study site. Although it is dangerous to extrapolate results without spatial or temporal replication, our collective experience since the mid-1980s working with coastal communities in Maine to enhance flats with hatchery-reared juveniles of *M. arenaria* is that the rate of natural predation observed in this study is not unusual for intertidal areas along the southern Maine coast. In the absence of direct measures to enhance juvenile clam survivorship during summer months when natural predation rates are high (i.e., applying protective netting to portions of the intertidal or modifying sediments using gravel or shell [e.g., Toba et al., 1992]), we recommend that local and state managers permit bloodwormers to harvest *G. dibranchiata* from flats closed for shellfish conservation purposes. If the objective of the closure is to protect large individuals (>30 mm SL), we recommend that managers review the work of Glude (1954) and Ambrose et al. (1998). Furthermore, limiting clamming in shellfish conservation areas where natural predation rates are high will likely not result in enhanced densities of small clams. Conservation closures for shellfish are more likely to benefit clams larger than 30 to 35 mm SL; that is, those individuals that have escaped the majority of threats by predators due to their relatively large size that enables them to burrow deeper in the sediments (Commito 1982).

Conflicts between various fisher groups who harvest intertidal organisms in Maine and elsewhere are likely to increase in future as prices for dwindling supplies of natural stocks of commercial marine species continue to increase against a backdrop of conditions that restrict or limit access to fisheries (e.g., management and/or rule-making decisions, local, state, and federal zoning laws, property rights issues, and aquaculture). Recently, it has become popular for fisheries managers to move toward decentralizing decision making and to spread out this process among communities, fishermen, and marine scientists (Wilson et al. 1994). Experimental approaches can be useful tools in helping to resolve ambiguities

and innuendos surrounding gear and other fisheries conflicts (Peterson et al. 1987, McAllister & Peterman 1992, Lenihan & Micheli 2000). This manipulative experiment demonstrated that local clam stewardship committees have a tool available to them to enhance survivorship of juvenile soft-shell clams. If adopted, this approach would necessitate short-term restriction of all types of digging of mud flats in fenced or netted areas during that time of year when clam predation and other sources of mortality are greatest. Conversely, if no attempts are made to deter predation on small clams, no changes in current rules and regulations are warranted.

ACKNOWLEDGMENTS

We thank the municipal marine wardens from the town of Brunswick, A. Houston and S. Catlin, for their assistance in the field and for the use of the town's airboat. D. Caton (Wiscasset) and P. Holman (Brunswick) represented local professional worm-ers and clammers, respectively. J. Hawkes, L. Larkin, D. Klemanski, J. MacLeod, D. Michaud, T. Murphy, K. Nakazawa, J. Rodzen, and T. Simeone also assisted in the field. J. Aspinall and J. Rodzen helped measure clams and worms and transcribe data. Conversations about experimental design and statistical analyses with S. Fegley were helpful. The paper was improved by critical comments from D. Wallace and an anonymous reviewer. We also thank D. Wallace for providing accommodations. This study was funded primarily by the town of Brunswick, Maine and by the Maine Department of Marine Resources (Augusta). Other financial contributors include the Maine Aquaculture Innovation Center (Orono, Maine, University of Maine at Machias, and the Gulf of Maine Council on the Marine Environment. The manuscript was prepared while B. Beal was a visiting Fulbright Professor at the National University of Ireland, Galway and he thanks the Zoology Department and staff at Árus de Brún for providing office space and supplies during his stay.

GENETIC VARIATION IN POPULATIONS OF THE COMMON CHINESE CUTTLEFISH *SEPIELLA MAINDRONI* (MOLLUSCA: CEPHALOPODA) USING ALLOZYMES AND MITOCHONDRIAL DNA SEQUENCE ANALYSIS

XIAODONG ZHENG,[1]* RUCAI WANG,[1] XIAOFENG WANG,[2] SHU XIAO,[1] AND BING CHEN[1]

[1]*Mariculture Research Lab, Fisheries College, Qingdao Ocean University, Qingdao, Shandong 266003, P. R. China;* [2]*Molecular Virology Lab, School of Medicine, Qingdao University, Qingdao, Shandong 266071, P. R. China*

ABSTRACT Allozymes and sequence of cytochrome oxidase subunit I (COI) gene were used to investigate the genetic variation in five populations of the common Chinese cuttlefish *Sepiella maindroni* in waters of China and Japan. Samples were examined at 14 enzymes comprising 23 putative allozyme loci. The results revealed moderate levels of genetic variability: the proportion of polymorphic loci = $0.226_{(0.99)}$, mean observed heterozygosities per locus = 0.038, mean expected heterozygosity per locus = 0.039, and the average effective number of alleles = 1.26. Nei's mean genetic distance ranged from 0.0001 to 0.0018.

Part of the cytochrome oxidase subunit I gene was amplified with the polymerase chain reaction (PCR) and sequenced for 27 individuals: five to six from each of the five populations. Sequence data showed that there were 11 variable nucleotide positions in the 661 base-pair segments of the gene, and the 27 sequences could be grouped into nine haplotypes (A–I). No remarkable genetic difference was observed among those populations.

KEY WORDS: genetic variation, *Sepiella maindroni*, allozyme, cytochrome oxidase I gene, DNA sequencing

INTRODUCTION

The cuttlefish *Sepiella maindroni* de Rochebrune, 1884, is widely distributed in Asia. It is an important and valuable fishery resource in China, Japan and South Korea (Dong 1991, Nesis 1987, Okutani 1995). Its output accounted up to about 60% of the total cephalopod production in 1980s in China, and occupies an important position in Chinese marine products (Qi 1998). But its yield has declined severely since then, due to over-fishing. One of the main reasons for the decline of population size is that aspects of its population biology are poorly documented, especially the population structure and genetic diversity.

Allozyme electrophoresis can provide direct information on the distribution of genotypes in accordance with the Hardy-Weinberg paradigm. It remains a valuable approach to describe breeding structure of a species (Carvalho & Nigmatullin 1998). Few genetic studies have been carried out on cuttlefishes, and all showed low levels of polymorphism (Pérez-Losada et al. 1996, Pérez-Losada et al. 1999). For providing useful information for resource management and protection, we examined four populations in the coastal waters of China, and one sample from Nagasaki port in Japan using allozyme electrophoresis. Intraspecific sequence variation within mtDNA has also proven a powerful tool for examining population structure in marine organisms (Carvalho & Pitcher 1994). The combination of mitochondrial DNA and allozyme analysis may be helpful in understanding the evolutionary dynamics of these interacting populations of marine species (Hilbish 1996). We further investigated genetic constitution of those populations through examining nucleotide sequence of part of the cytochrome oxidase subunit I (COI).

MATERIALS AND METHODS

Samples

Fresh samples were randomly collected from five locations in the waters around China and Japan (Fig. 1, Table1), and kept frozen at −20°C until dissection. Mantle length of all the specimens was measured and sex were recorded (Table 2). Mantle muscle tissue, liver, eyes and buccal muscle were taken from each individual in ice as quickly as possible, then transferred for storage at −80 C allozymic analyses. Muscle samples were removed and kept in liquid nitrogen for DNA analysis.

Allozymic Analysis

Electrophoresis was carried out using standard horizontal starch gel techniques (Harris & Hopkinson 1976), essentially as described by Zheng et al. (2001b). Forty-six putative enzyme-

coding loci and 4 different kinds of tissues of *S. maindroni* (e.g. liver, eyes, mantle and buccal muscle) were screened using several enzyme-staining recipes (Shaw & Prasad 1970, Shaw & Prasad 1990, Morizot & Schmidt 1992) in a range of buffer systems.

After preliminary experiments for some specimens from five populations, 14 enzymes and optimal buffer systems and tissue (Table 3) were selected for further research.

Allele frequencies were estimated for each sample, together with several measures of genetic diversity. The proportion of polymorphic loci (P), values of the observed heterozygosity (H_o), the expected heterozygosity (H_e), and the effective number of alleles (N_a) were calculated by direct census of the population data. Two criteria of polymorphism were used: $P_{0.99}$ and $P_{0.95}$. Nei's (1972) genetic distance (D_{Nei}) was calculated to quantify the genetic divergence between cuttlefish samples. Dendrogram to illustrate the genetic relationship among five populations was constructed from genetic distance using the unweighted pair-group arithmetic mean (UPGMA) cluster-analysis algorithm (Sneath & Sokal 1973).

DNA Extraction, Amplification and Sequencing

Total genomic DNA was extracted using a CTAB method modified from Winnepenninckx et al. (1993). The target DNA segments were amplified by PCR. The primers used for the amplification of partial COI gene were: HCO2198 (5′-TAA ACT TGA GGG TGA CCA AAA AAT-3′) and LCO1491 (5′-GGT CAA CAA ATC ATA AAG ATA TTG-3′) from Folmer et al. (1994). PCR amplifications were performed under the following conditions: 120s at 94°C, then 30 cycles of 40s at 94 C, 1 min at 50°C, and 1 min at 72°C. A total volume of 25 μl. reactions consists of 0.5 units of *Taq* (TaKaRa), 0.5 μM each primer, 0.2 μM each dNTP, 2.5–3.5 mM $MgCl_2$, 2.5 μl of 10 × buffer supplied with *Taq* and 4μl (30–50 ng) of template DNA.

The amplified fragments were purified by the PCR fragment recovery Kit (TaKaRa). Purified products were sequenced directly using the ABI PRISM BigDye Terminator cycle sequencing Ready Reaction Kit and AmplicTaq DNA polymerase with ABI PRISM 377XL DNA sequencer (Applied Biosystem Inc.). All final sequences were obtained from both DNA strands for verification.

Phylogenetic and Sequence Difference Analyses

The sequences were aligned with other gene sequences (outgroup species) using a computer-assisted procedure, Clustal W (Version 1.80) (Thompson et al. 1994). No gaps were found in the COI sequences. The extent of sequence difference between individuals was calculated by averaging pair-wise comparisons of sequence difference across all individuals. One thousand bootstrap replicate data sets were produced using SEQBOOT. Under the Maximum Likelihood model, the sequence similarity and genetic distance were calculated with PHYLIP 3.5c (Felsenstein 1995). Distance-matrix trees were then constructed using the Fitch and Margoliash (1967) least-squares (LS) method and the neighbor-joining (NJ) method (Saitou & Nei 1987). *Sepia officinalis* was taken as the distant outgroup species (Carlini & Graves 1999, Accession no. AF000062).

RESULTS

Description and Interpretation of Allozymes

Of the 14 enzymes assayed routinely, 15 loci (AAT-2*, ALP*, CK*, EST-2* FBP*, G3PDH-2*, GPI-1*, GPI-2*, GRS-1*, GRS-2*, IDHP-1*, MPI-1*, MPI-2*, PGM-1*, SOD*) were monomorphic in all samples, while the others (AAT-1*, EST-1*, G3PDH-1*, GPI-3*, IDHP-2*, NP*, PGDH*, PGM-2*) showed the most common allele frequencies were less than 0.99 in at least one sample. Allozymes that were consistently and clearly scored in all samples were considered useful genetic markers for population analysis. Genetic variability was estimated by the proportion of polymorphic loci and average heterozygosity. P, the proportion of polymorphic loci ranged from 0.043 to 0.217(<0.95) and from 0.217 to 0.261 (<0.99), respectively. When five samples were

Mean heterozygosities per locus = 0.038(H_o); 0.039(H_e)

The average effective number of alleles = 1.26

TABLE 5.

Genetic similarity (I) and genetic distance (D_{Nei}) among five samples in the cuttlefish *Sepiella maindroni*

Samples	Nagasaki	Putian	Nan'ao	Shenzhen	Zhanjiang
Nagasaki		0.9993	0.9996	0.9994	0.9982
Putian	0.0007		0.9999	0.9998	0.9992
Nan'ao	0.0004	0.0001		0.9999	0.9992
ShenZhen	0.0006	0.0002	0.0001		0.9994
Zhanjiang	0.0018	0.0008	0.0008	0.0006	

pooled, $P_{0.95} = 0.147$; $P_{0.99} = 0.226$. Mean heterozygosities per locus (observed and expected), and the effective number of alleles per locus were presented for all of the five populations pooled (Table 4).

Genetic similarity (I) and genetic distance (D_{Nei}) between all samples based on the 23 loci were given in Table 5. Nei's D of *S.maindroni* populations varied from 0.0001 to 0.0018 (Table 5).

Comparison of observed genotypic frequencies with Hardy-Weinberg expectation did not show significant deviation ($P > 0.05$) at NP* loci of five populations. The expected values of the genotype frequency were smaller than five in other polymorphic loci, so a χ^2 test for the Hardy-Weinberg equilibrium could not be performed. The dendrogram was constructed from Nei's D value (Fig. 2.)

Sequence Variation of the COI Gene

A base-pair (bp) (661) segment of the COI gene was sequenced for 27 individuals from five locations (NG, PT, NA, SZ and ZJ). Target segments were given by base pairing.

The A + T percentage of 5 samples ranged from 68.38% to 68.99% (Table 6), which is a little higher than *S. officinalis*'s (63.47%) (Carlini & Graves 1999)

Among these individuals, eleven nucleotide positions (position 146, 197, 263, 317, 362, 497, 543 and 617) were found to be variable (Fig. 3). As expected, ten variation sites were at third position of codon triplets, and only one variation site (position 621) was at 1st position of codon triplets (Fig. 3). The base of positions 621 and 623 occurred to transverse from A to T at the same time in four individuals checked, and finally resulted in compatible amino acid change, in which Cys was in place of Ser. The other base substitutions were silent (synonymous) changes that do not result in amino acid change.

Analysis of Relationships and Occurrence Frequency of Haplotypes

Nucleotide sequence difference between 27 individuals from Nagasaki in Japan to Zhanjiang in South China Sea ranged from 0.00 to 1.21%. Among these individuals, nine unique haplotypes (A–I) were found (Table 7). The haplotype D, with a frequency of 48% (13/27), was most commonly observed in all samples, though it was found only in the 4 populations living in the coastal waters of China. The haplotype A followed, and its highest frequency (4/6) was found in NG. The haplotype E was found in PT and ZJ. The other haplotypes were found each in only one individual.

According to the phylogenetic tree of Neighbor-Joining (Fig. 4) and UPGMA (Fig. 5), there were two main branches: most of NG (67–83%) occupied one position from one branch, and the individuals (81–86%) living in the coastal waters of China took up the other branch. But genetic distance of 27 individuals as revealed by

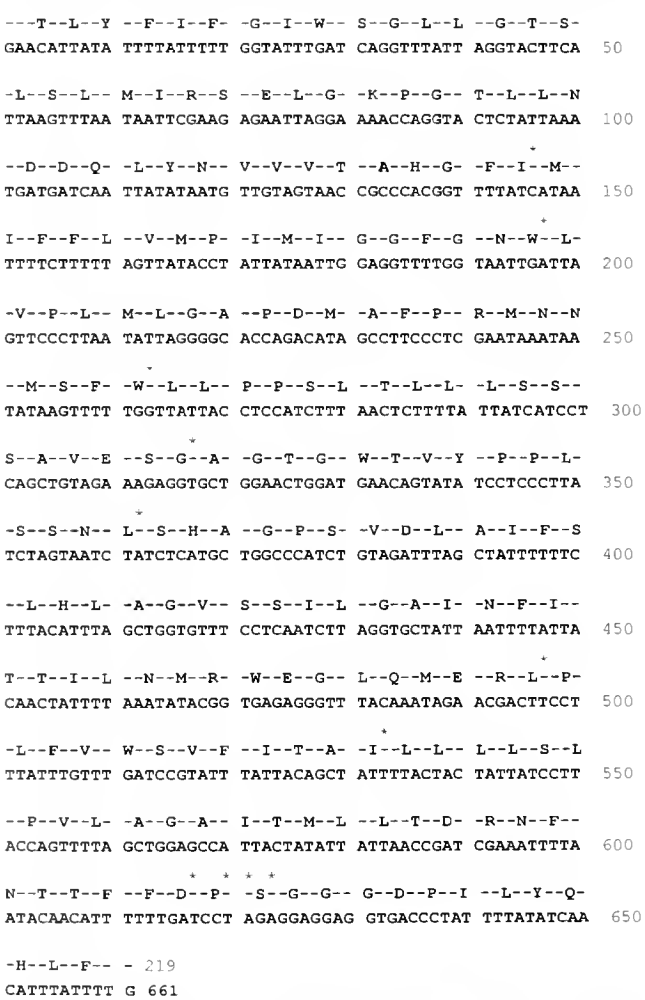

Figure 3. Nucleotide and deduced amino acid sequences of partial COI gene fragment in *S. maindroni*. Asterisks above the sequence show the variation nucleotide positions.

A: adenine; C: cytosine; G: guanine; T: thymine

the COI sequence ranged from 0.0000 to 0.0076 using PHYLIP 3.5c. Geographical proximity had no remarkable relevance to genetic-phylogenetic relationships among these haplotypes.

DISCUSSION

The study of enzyme loci in five populations of *S. maindroni* showed that this species had low levels of variability. The mean H_o(0.038) falls below the average for invertebrate and molluscs (0.120 and 0.145, respectively) (Ward et al. 1992), and also for marine molluscs (0.147) (Fujio 1997), but within the range for cephalopods (0.03 ± 0.03) (Zheng et al. 2001a). Low levels of heterozygosity have been found in other species of Cephalopoda, such as *Loligo gahi, Illex argentinus* (Carvalho & Pitcher 1989, Carvalho et al. 1992), *Sepioteuthis lessoniana* (Izuka et al. 1994), *Sepia officinalis, S.orbignyana, S.elegans* (Perez-Losada et al. 1996). Very low levels of genetic variability are apparently a common facet of cephalopods except *Berryteuthis magister* (H_o = 0.131) (Katugin 1993), a feature probably unique over any major group of invertebrates.

In the five populations, the proportion of polymorphic loci of NG was the lowest ($P_{0.95}$ = 0.043), and ZT was the highest. The sample of NG was obviously different from other samples at loci of AAT-1*, EST-1*, GPI-3*, IDHP-2* and PGDH*. The fixed allelic differences at AAT-1* between NG and other samples in coastal waters of China could serve as valuable markers to monitor geographic variation in stock distribution, though the genetic distance was low (maximum value of D = 0.0018 being found between the NG and ZJ samples).

Populations undergoing severe bottlenecks with rapid reductions in population size may lose rare alleles through genetic drift (Wright 1978). Severe fishing pressure could bring about such population declines, especially if populations were founded each year by relatively few individuals. Population crashes are more likely in commercially harvested species (Nelson & Soule 1987), particularly when production models over-estimate escapement rates. In annual species such as *S. maindroni*, the genetic implications of bottlenecks are particularly significant since there are no overlapping year classes to serve as a repository for genetic diversity. For instance, in China, the cuttlefish *S. maindroni* had once become one of the four biggest fisheries in the East China Sea. But now, its position has been replaced by other cephalopods. Clearly, it is facing the danger of extinction. A bottleneck effect may be one of the reasons for the low diversity of *S. maindroni* populations.

The present COI gene analysis suggests that there was no remarkable genetic differentiation in the five samples, though there was evidence to indicate that NG samples differ slightly from the other samples in the coastal waters of China, especially in the number and type of haplotypes and the position in UPGMA and NJ trees. The result also supported the conclusion of biochemical research.

Pelagic organisms in the open ocean were generally regarded as having low levels of population differentiation, resulting from probably ample opportunities of dispersal in various life history stages and the lack of physical barriers in the environment. The study on the population genetic structure of large pelagic fishes and some cephalopods in the open oceans, such as swordfish and

diamond-shaped squid, showed very low levels of genetic diversity (Rosel & Block 1996, Kitaura et al. 1998).

The cuttlefish *S. maindroni* is distributed widely in Asia—in the sea of Honshu (Japan) to the north, Malaysia and the Philippine Islands to the south, and Indian Ocean to the west. The present study suggests that for *S. maindroni*, much like a pelagic species with considerable mobility, behaves so that all the populations covered in this study may have migrated into each other and no physical barriers existed in the environment, especially regarding the samples from PT to ZJ.

Genetic diversity in populations of the cuttlefish needs to be further examined with more extensive data from different geographical populations and also from more DNA markers such as highly variable microsatellite DNA markers.

ACKNOWLEDGMENTS

We are grateful to Prof. Yutaka Natsukari for generously providing reagents and lab space for allozyme analysis. We thank Dr. T.X. Gao, Z.G. Chen, for their valuable suggestions and help on data analysis. We also thank X.D. Du, X.Z. Lin, M.Z. Zeng, W.Z. Chen, J.M. Zhao, for assistance in the collection of samples. SEASONAL VARIATION IN PHYSIOLOGICAL CONDITION OF *AMBLEMA PLICATA* IN THE UPPER MISSISSIPPI RIVER

EMY M. MONROE AND TERESA J. NEWTON*·†

U.S. Geological Survey, Biological Resources Division, Upper Midwest Environmental Sciences Center, 2630 Fanta Reed Road, La Crosse, Wisconsin 54603

ABSTRACT Measures of physiological condition are being used as sub-lethal endpoints in studies with unionids exposed to a variety of stressors, yet the natural seasonal variation in these measures are largely undocumented. We measured concentrations of glycogen in foot and mantle tissue and a tissue condition index (TCI) in *Amblema plicata* (Say 1817), about monthly, for 2 years in mussels that were: (1) obtained directly from the Upper Mississippi River (riverine group); and (2) relocated from the river into an artificial pond (relocated group). In both groups, we observed significant seasonal variation in all physiological indicators. Seasonal variation in glycogen was 72% in mantle and 52% in foot tissue and paralleled reproductive activity in this short-term breeder. In the relocated group, most of the variation in glycogen occurred during the first six months after relocation, suggesting that handling stress may have been a contributing factor. The significant seasonal variation in the TCI paralleled glycogen in riverine mussels. We observed tissue-specific differences in glycogen in the riverine group, but not in the relocated group. These data suggest that an interaction of environmental and biological factors influence the energetic status of mussels in natural populations. A better understanding of this variation is needed to interpret changes in physiological condition due to stressors such as relocation.

KEY WORDS: glycogen, condition index, seasonal variation, *Amblema plicata*, relocation

INTRODUCTION

Unionids are the most imperiled group of animals in North America with 72% of the 297 species classified as extinct, endangered, threatened, or listed as a species of special concern (Williams et al. 1993). Declines in species density and diversity have been attributed to habitat degradation, changes in fish host distributions, commercial exploitation, and introduced species (Bogan 1993). Thus, many agencies are examining approaches to conserve this fauna. Relocation is being used extensively as both a conservation and management tool (Cope & Waller 1995), however, it is difficult to draw conclusions on the relative success of relocations because of inconsistencies in the methods used and in the selection of endpoints. Often, survival and growth are the only endpoints measured and they are usually monitored for <1 yr (Cope & Waller 1995). However, one-year survival estimates may underestimate the mortality that occurs during longer relocations (Newton et al. 2001), and short-term measures of growth may be of limited value for these long-lived animals (Naimo et al. 1998).

Research suggests that changes in certain physiological measures often precede changes in survival (Haag et al. 1993). However, Newton et al. (2001) were unable to predict mortality in *Amblema plicata* based on physiological indicators measured annually over a three- to four-year period. This lack of predictive power may have been related to the frequency of measurement or because the measures were not sensitive enough. It is difficult to draw conclusions about the physiological condition of unionids from measurements made at a few points in time without understanding the seasonal variation in such measures.

Various sub-lethal indicators have been examined in unionids. TCI has been used to assess the condition of freshwater bivalves exposed to zebra mussels (Baker & Hornbach 1997) and contaminants (Naimo et al. 1990), or infected with parasites (Jokela et al. 1993). Because the measurement of condition indices requires sacrificing the individual, their application is limited. More recent techniques allow tissues to be biopsied for physiological and biochemical constituents (Berg et al. 1995, Byrne & Vesk 1996, Naimo et al. 1998). Glycogen is the primary storage form of carbohydrates in bivalves; consequently, it is being used as a physiological indicator in unionids subjected to emersion stress (Greseth 1998), quarantine and relocation (Patterson et al. 1997, Naimo et al. 1998), zebra mussel infestation (Haag et al. 1993, Hallac & Marsden 2000) and parasitic infestations (Jokela et al. 1993).

The few studies measuring seasonal variation in physiological indicators in natural populations suggest that much of this variation is related to environmental conditions or reproduction (Dietz & Stern 1977, Holopainen 1987, Pekkarinen 1993). For example, monthly sampling of *Sphaerium transversum* for total protein and carbohydrates showed a positive correlation with reproductive activity during the fall and winter and a decline towards the end of the reproductive season (Dietz & Stern 1977). Pekkarinen (1993) found the periods of gravidity for *Unio pictorum* and *U. tumidus* were correlated with rising and maximum water temperatures and condition indices rose concomitant with the rise in water temperatures. Seasonal changes in the physiological condition of unionids is a complex process involving, at a minimum, environmental conditions and the energetic demands of reproduction.

Most studies have measured physiological condition at one point in time in response to a given stressor. In addition, most of these studies measured seasonal variation in physiological indicators on bivalves with substantially different reproductive cycles than unionids. Information on the seasonal variability in physiological measures in individuals is largely undocumented. Thus, our objectives were to (1) examine the seasonal variation in glycogen concentrations and a TCI in two groups of *A. plicata*, an undisturbed riverine group and a relocated group; and (2) compare seasonal patterns in glycogen between foot and mantle tissue.

MATERIALS AND METHODS

We examined the seasonal variation in glycogen concentrations and in a TCI in two groups of *A. plicata*: a riverine group and a relocated group. For the riverine group, we obtained 10 zebra-

*Corresponding author. E-mail: Teresa_Newton@usgs.gov †Published formerly as Teresa J. Naimo

mussel-free individuals (80–90 mm shell length) about monthly from May 1997 to October 1998 from Lake Onalaska, a riverine lake in the Upper Mississippi River, near La Crosse, WI. For the relocated group, we relocated 200 zebra-mussel-free individuals (80–90 mm shell length) from the Upper Mississippi River into an 0.04 ha earthen pond supplied with well-water at the Upper Midwest Environmental Sciences Center in La Crosse, WI, in May 1995. Ten individuals were obtained from the pond for analysis about monthly until November 1996. Although no supplemental food was added, the pond produced extensive blooms of green algae each summer. Because these two groups were sampled during different years, we have made no attempt to compare results between groups; rather, we are examining seasonal patterns in physiological measures within a group and between tissues within a group.

To obtain tissues for analysis, 50–100 mg pieces of foot and mantle tissue were removed from sacrificed animals, placed on dry ice, and stored at −84°C until analyzed for glycogen. Tissue samples were consistently removed from the same area (Naimo & Monroe 1999). The remainder of the soft tissues and shells were dried to a constant weight at 105°C for determination of the TCI, calculated by dividing the tissue dry mass by the shell dry mass and multiplying the quotient by 100. For the relocated group, TCI analysis was conducted only in 1996. Because *A. plicata* are not sexually dimorphic, the sex of individuals was not determined. Concentrations of glycogen were determined by the alkaline digestion and phenol-sulfuric acid spectrophotometric method (Naimo et al. 1998).

The accuracy of glycogen determinations was quantified by the use of procedural blanks, replicates of an in-house reference material (Naimo et al. 1998), triplicate analysis of 4 aqueous calibration standards, and triplicate analyses of 3 known additions or 3 matrix standards. Glycogen in the tissue samples averaged 0.17 mg (range, 0.03–0.97) in foot tissue and 0.29 mg (range, 0.04–1.86) in mantle tissue. As a measure of precision, we estimated the relative standard deviation of triplicate analyses of known additions according to APHA et al. (1995). Relative standard deviations averaged 8% in foot tissue and 12% in mantle tissue. Bias associated with our glycogen determinations was estimated by recovery of matrix standards and known additions (APHA et al. 1995), mean percent recovery of glycogen averaged 106% in foot tissue and 99% in mantle tissue.

We assumed glycogen concentrations (mg/g dry weight) followed a gamma distribution. The gamma distribution is a plausible model for random variables, like glycogen concentration, that cannot take values less than zero and for which the variance is approximately proportional to the squared mean (McCullagh & Nelder 1989). We used the model for mean glycogen concentration in tissue j from group i, μ_{ij}, given by:

$$\mu_{ij} = \mu_0 \exp\left[\tau_j + \beta \log(t) + \beta_j \log(t) + \gamma_1 \sin\left(\frac{2\pi t}{12}\right) + \gamma_2 \cos\left(\frac{2\pi t}{12}\right)\right], \quad (1)$$

where μ_0 is the baseline (mantle tissue from mussels in the pond) mean glycogen concentration, τ_j is the effect of tissue type (foot or mantle), t is time measured in months since the start of the year during which the trial began, β is a trend coefficient, β_j is a trend coefficient due to tissue j and γ_1 and γ_2 are coefficients in a sinusoidal seasonal effect at a frequency of one cycle per year. This model allows us to detect long-term trends in glycogen, including seasonal effects that can be described by a sinusoidal response, and possible differences between tissues in each group. We modeled Var(μ) by:

$$Var(\mu) = \frac{\mu^2}{\phi}, \quad (2)$$

where ϕ is a scale parameter. Log(μ) can be viewed as a generalization of analysis of covariance that accommodates a gamma-distributed response, one categorical main effect (tissue), a sinusoidal seasonal effect, and a logarithmic trend that may differ between tissues. We fitted the model given by equations (1) and (2) using maximum likelihood estimation. We modeled the mean TCI similarly to the model given above for glycogen, except the parameters for tissue type were removed.

RESULTS

In the riverine group, glycogen and the TCI varied significantly on a seasonal basis (glycogen $P = 0.02$, TCI $P < 0.0001$), and showed a similar pattern in both years with highest values early in the season (usually June) and lowest values late in the season (usually October; Fig. 1). Although a significant seasonal pattern was apparent in all indicators, it was most pronounced in glycogen in mantle tissue. For example, glycogen concentrations varied 72% [(annual maximum − annual minimum) / annual maximum) × 100], during 1997 and 46% during 1998 (Fig. 1). In contrast, the seasonal change in TCI varied only 20% during 1997 and 38% during 1998. Although seasonal patterns in glycogen and TCI were similar in both years, the annual maximum of glycogen in foot and mantle tissue was greater in 1997 than in 1998, while TCI maximums were similar between years.

In the relocated group, glycogen and the TCI also varied seasonally (glycogen $P = 0.01$, TCI $P = 0.002$). Like the riverine group, highest values were observed early in the season (usually May) with lower values each fall (usually November). Most of the seasonal variation in physiological measures in this group were likely driven by the large decline in glycogen the first 6 months after the relocation (Fig. 1). Glycogen values declined by 72% in mantle tissue and 65% in foot tissue from May to November 1995. During 1996, glycogen concentrations continued to decline, but only by 35% in mantle tissue and 49% in foot tissue.

Glycogen concentrations varied between foot and mantle tissue in the riverine mussels ($P < 0.0001$), but not in the relocated mussels ($P = 0.09$). In the riverine group, glycogen concentrations in mantle tissue ranged from 1.9 to 3.6 times those in foot tissue over both years. In the relocated mussels, glycogen concentrations in foot and mantle tissue were similar during both years (Fig. 1).

DISCUSSION

The significant seasonal variation in glycogen was anticipated, given that glycogen is the primary reserve energy store and is re-allocated from the body towards the gonads during gametogenesis (Gabbott 1983). It is difficult to compare the amount of annual variation in glycogen concentrations in our riverine group (range, 32–72%) with other studies because few have measured glycogen with the frequency that we used and several have used species with substantially different reproductive traits. However,

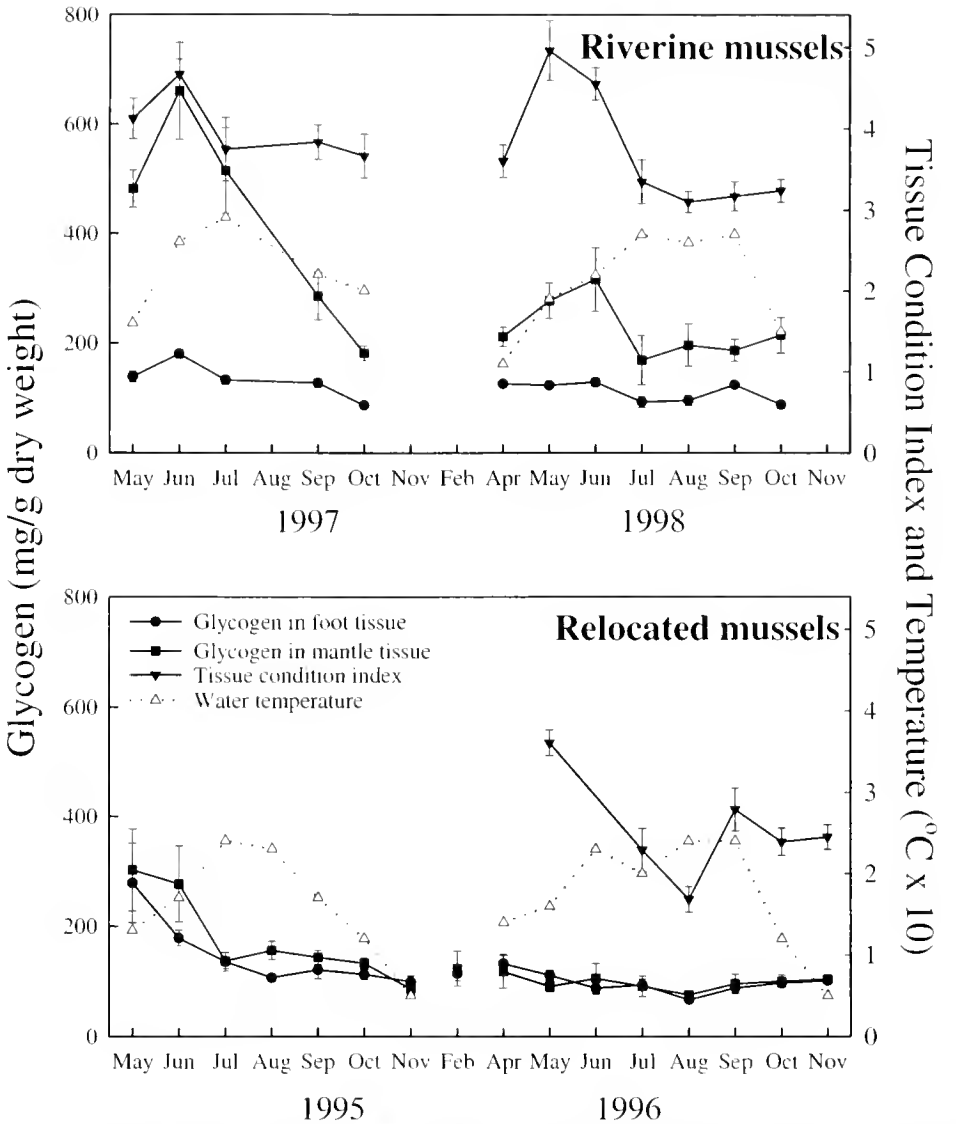

Figure 1. Mean (±1 SE) concentrations of glycogen and the tissue condition index in *Amblema plicata* (solid lines) and mean water temperature (dotted lines). Riverine mussels were sampled from the Upper Mississippi River about monthly from May 1997 to October 1998. Relocated mussels were removed from the Upper Mississippi River and placed into an earthen pond (May 1995), then sampled about monthly until November 1996.

total body glycogen content varied 39% between July and October in *Anodonta piscinalis*, during the time of glochidial development (Jokela et al. 1993). Similarly, the total carbohydrate content of fingernail clams (*S. transversum*) varied 80% when sampled monthly in a given year (Dietz & Stern 1997). Thus, it seems that significant seasonal variation exists in glycogen concentrations in a variety of freshwater bivalves, even those with substantially different reproductive strategies.

Seasonal variation in glycogen concentration is likely driven by environmental factors such as water temperature, which subsequently influences reproductive condition. *A. plicata* is a short-term breeder with maturing gametes and glochidia present from May to early August in the Upper Mississippi River (Holland-Bartels & Kammer 1989). By late May, 100% of the females and 80% of the males contain mature gametes, indicating a progression towards full reproductive maturation as water temperatures rise from 13° to 19°C (Fig. 2). Seasonal patterns in glycogen concentration in riverine mussels in this study parallel reproductive activity. As water temperatures warm in the early spring, male and female mussels begin producing mature gametes and glycogen is either being stored or is re-allocated from other tissues to meet the energetic demands of reproduction. As temperatures begin to stabilize in late June, gametes are fertilized, mature glochidia are released, and glycogen concentrations are depleted (Fig. 2).

Condition indices are frequently used as a measure of nutritive status in marine bivalves and represent the total energetic status of an individual, including stores of protein, lipids, and carbohydrates (Bayne et al. 1985). Thus, seasonal patterns in condition indices should follow food availability and reproductive status. In the riverine mussels in this study, seasonal patterns in the TCI paralleled reproductive activity. Prior to reproduction (April to June), the condition of mussels increased (they were adding soft tissue

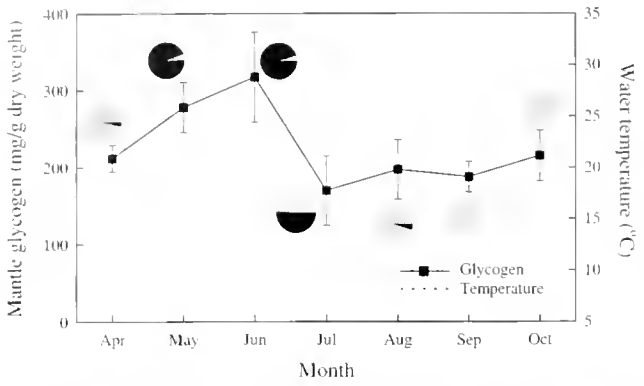

Figure 2. Mean (±1 SE) concentrations of glycogen in mantle tissue in *Amblema plicata* from the Upper Mississippi River during 1998 (solid line), and water temperature at the time of mussel collection (dotted line). Pie charts estimate the reproductive stage in *A. plicata* with the black area representing the percentage of male and female mussels on each date containing mature gametes (data from Holland-Bartels & Kammer 1989).

weight) as they prepared for reproduction. After fertilization and glochidia release (June to July), energetic stores were depleted and the TCI decreased. This coupling of the condition index and the reproductive cycle was also seen in the short-term breeders *U. tumidus* and *U. pictorum* (Pekkarinen 1993).

The similarity in the seasonal patterns between glycogen and the TCI in riverine *A. plicata* suggests that in natural populations, glycogen represents a large proportion of the total energy stored. In another short-term breeder, *Quadrula pustulosa*, carbohydrates averaged 76% of the total energy stores (Greseth 1998). Conversely, in relocated mussels, patterns in glycogen and the TCI become uncoupled, suggesting that energetic stores besides glycogen are being used. In natural populations, we hypothesize that measures of glycogen and the TCI provide comparable data on the relative condition of an individual, but when unionids are stressed, such as during relocation, these two measures provide different data, reflecting varying energy sources during periods of stress. If this can be shown for additional species, resource managers may have another tool for use in studies with threatened and endangered species.

The substantial difference in glycogen between tissues in riverine mussels, but not in relocated mussels, suggests that energy stores may be re-allocated during periods of stress. These data support our earlier conclusions that glycogen may be preferentially stored in mantle tissue in *A. plicata* when environmental conditions are favorable (Naimo & Monroe 1999). Jokela (1996) found that energy was allocated differently among reproduction, somatic growth, and biochemical storage, depending on the time of the year when *A. piscinalis* were transplanted. Thus, because the relocated mussels were moved during an active reproductive period, the glycogen that had accumulated in mantle tissue may have been re-allocated to maintenance metabolism.

The seasonal variation in physiological measures in native populations indicates that numerous biological and environmental parameters interact to influence the relative condition of unionids. Researchers measuring physiological responses of unionids to a particular stressor (zebra mussels, contaminants, relocation, etc.) at a given time need to understand where these measures fall on the natural response curves to better interpret how a given stressor affects the physiological energetics of the species under consideration. Finally, this research was conducted on a single species; studies with other species are critically needed before resource managers can make sound management decisions that will conserve this declining faunal group.

ACKNOWLEDGMENTS

We thank staff from the Wisconsin Department of Natural Resources, La Crosse, WI, for obtaining mussels for the relocation portion of this study. Steve Gutreuter from the Upper Midwest Environmental Sciences Center provided statistical guidance.

EFFECTS OF STOCKING DENSITY ON GROWTH AND SURVIVAL OF ATLANTIC SURFCLAMS IN BOTTOM CAGES VERSUS MESH BAGS

RANDAL L. WALKER*

Shellfish Aquaculture Laboratory, University of Georgia Marine Extension Service, 20 Ocean Science Circle, Savannah, Georgia 31411-1011

ABSTRACT Atlantic surfclams, *Spisula solidissima*, were reared in field culture to determine the effects of: (a) stocking densities on clams cultured in bottom cages and mesh bags; (b) bottom cage versus mesh bag culture; and (c) bag mesh diameter on growth and survival of clams in coastal Georgia. With the exception of the 100 stocking density, mean clam size decreased with increases in stocking densities in cages, i.e., 200 clams/m^2 ($\bar{x}$ = 56.5 mm) = 300 ($\bar{x}$ = 57.0 mm) > 100 ($\bar{x}$ = 52.8 mm) > 400 ($\bar{x}$ = 49.1 mm) = 500 ($\bar{x}$ = 51.0 mm) > 600 ($\bar{x}$ = 46.5 mm). No significant difference ($p = 0.1994$) in clam survival occurred among any cage treatments; however, mean survival of clams ranged from 52% in cages stocked at 300 clams/m^2 to 87% in cages stocked at 500 clams/m^2. Significant differences ($p = 0.0258$) in clam survival occurred among the mesh bag stocking density treatments with survival ranging from 22% in densities of 100 clams/m^2 to 73.5% at 500 clams/m^2. In the mesh bags, clam size was significantly greater in the 200 clams/m^2 ($\bar{x}$ = 32.9 mm) = 400 clams/m^2 ($\bar{x}$ = 32.8 mm) = 500 clams/m^2 ($\bar{x}$ = 34.6 mm) treatments than 300 clams/m^2 ($\bar{x}$ = 29.4 mm) which were greater than the 100 clams/m^2 ($\bar{x}$ = 26.6 mm) bag treatment. Atlantic surfclams had significantly ($p = 0.0100$) higher survival in 3-mm mesh (62%) versus 6-mm mesh bags (18.5%) with low survival (0.3%) in 12-mm mesh bags. Clam size was similar ($p = 0.0623$) in all three mesh size treatments. Atlantic surfclams had greater growth and survival rates with greater production in bottom cages over mesh bags for the field culture of clams in Georgia. A culture strategy using stocking density data for maximizing the harvest, hence marketing window of the Atlantic surfclam, is discussed.

KEY WORDS: *Spisula*, growth, mortality, stocking density, cage, bag, mesh

INTRODUCTION

The Atlantic surfclam, *Spisula solidissima* (Dillwyn, 1817), natural fishery was valued at $30.4 million in the United States in 1999 (O'Bannon 2000). Atlantic surfclams occur from shore to 40 m depth offshore, from the maritime provinces in Canada to South Carolina (Abbott 1974). However, the fishery is centered primarily between New York and Virginia. Large adult clams greater than 12 cm in shell length (L) are harvested and used in the fried clam strip and chowder markets (Goldberg 1989).

The Atlantic surfclam does not naturally occur in Georgia; however, a subspecies *Spisula solidissima similis* does occur (Walker & Heffernan 1994). The southern surfclam, *Spisula solidissima similis* is now classified as *Spisula raveneli* (Conrad, 1831) (American Fisheries Society 1998). Insufficient stocks of *Spisula raveneli* occur in coastal Georgia to support a fishery (Walker & Heffernan 1994). The Atlantic surfclam cannot survive the summer water temperatures in coastal Georgia, whereas the southern surfclam survives the first summer, but generally dies during the second summer (Walker & Heffernan 1994).

Research into the development of an Atlantic surfclam aquaculture fishery in Georgia has shown promise (Goldberg & Walker 1990; Walker & Heffernan 1990a, Walker & Heffernan 1990b, Walker & Heffernan 1990c). Earlier growth studies examining the feasibility of culturing the northern Atlantic surfclam in Georgia showed that surfclams grow well over winter, but die by summer (Goldberg & Walker 1990, Walker & Heffernan 1990a, Walker & Heffernan 1990b, Walker & Heffernan 1990c). Atlantic surfclams (10 mm in L) when field planted in October after water temperatures drop below lethal levels (28°C) in Georgia will grow 50 to 70 mm L by the following spring. Thus, marketable size Atlantic surfclams can be grown in 6 months as compared to 2 to 2.5 years of growth required for culturing the native northern quahog, *Mercenaria mercenaria* (Linnaeus, 1758) (Walker 1997).

The potential for aquaculture for Atlantic surfclams is to produce clams (approximately 50 mm L) for the lucrative fried, raw and steamer markets. The rapid growth rate of the clam in Georgia allows a marketable product in six months from field planting. Extension efforts in developing an aquaculture industry for surfclams has also shown promise. Taste tests at local seafood festivals in Georgia indicated that the clam has potential for development into an aquaculture industry (unpublished data). Taste testers rated the clam as an excellent product with a slight sweet and mildly nutty flavor; however, clams must be placed in floating cages for a brief period to allow clams to purge sand from inside their shell prior to marketing. Marketing attempts with local seafood dealers showed that they could sell the clam at an equivalent price to that of the northern quahog. The only drawback of the marketing attempts was that the Atlantic surfclam had a short shelf life. A preliminary attempt at flash freezing the clams and placing them in shrink packing, resulted in the cracking of the shells. The shells were weak presumably due to the rapid growth rate of clam. Clams were increasing their length and width at the margins of the shell rather than producing a thick layer of shell. Another problem in developing an aquacultural industry for surfclams in Georgia is that clams need to be harvested, sold, and consumed in a very short period (May). One possible means of increasing the marketing window and increasing shelf life, may be to harvest clams earlier in the season prior to the warmer waters adding an increased physiological stress level on the animal. By manipulating field stocking densities of surfclams in culture units, a clam farmer may optimize growth conditions producing a harvestable product earlier in the season.

This study examines the effects of cage and mesh-bag stocking densities on the growth and survival of cultured surfclams in the coastal waters of Georgia in an effort to optimizing the field harvesting window of opportunity. In addition, the study determines

the effects of bag mesh size on growth and survival of the Atlantic surfclam.

MATERIALS AND METHODS

Cage Stocking Density Study

To determine the effects of cage stocking density on growth and survival of Atlantic surfclams, cages were stocked with Atlantic surfclams of 15.5 ± 0.17 (S.E.) mm L at treatment densities of 100, 200, 300, 400, 500, and 600 clams per cage. Each treatment had three replicate cages. Eighteen 6-mm mesh vinyl-coated-wire cages (1 × 1 × 0.6 m) were partially buried (0.3 m) in a sandy-mud substrate in a straight line at the spring-low-water mark on an intertidal flat at the mouth of House Creek, Little Tybee Island, Georgia. Two 1-m poles (to anchor cages) were driven into the sediment at opposite corners of each cage and attached to the cage with cable ties. Cages were randomly stocked according to a random number table in October 5, 1995. Cages were harvested 222 days later in May 14, 1996 with all clams per cage counted and 50 randomly selected clams measured for shell length (anterior-posterior) to the nearest 0.5 mm with Vernier calipers..

To determine the effects of stocking density on growth utilizing the mesh-bag-line culture system designed for the culture of the northern quahog (Walker & Hurley 1995), surfclams were stocked at various densities in 6-mm mesh bags. Five mesh bags (0.5 m^2 each) were attached to a long line according to Walker and Hurley (1995). Atlantic surfclams at 15.5 ± 0.17 mm were stocked at densities of 50, 100, 150, 200, and 250 clams per bag with three replicate bags per treatment. These stocking densities are equivalent to densities of 100, 200, 300, 400, and 500 clams/m^2, respectively. Results are reported in terms of clams/m^2 to compare with the same density as in the cage experiment. Bags were randomly assigned to long lines and were deployed in October 5, 1995. Bag lines were secured with stakes adjacent to the cages. Clams were harvested in May 14, 1996 with all clams per bag counted and 50, if available, randomly selected clams measured for shell length (anterior-posterior) to the nearest 0.5 mm with Vernier calipers.

Mesh Size Study

To determine the effects of bag mesh diameter on growth and survival of Atlantic surfclams, 3-mm (N = 4), 6-mm (N = 3), and 12-mm (N = 3) mesh bags were stocked with 200 Atlantic surfclams at a mean size of 15.5 ± 0.17 mm. Five bags each were randomly attached to two long lines (Walker & Hurley 1995) and staked at 0.5 m below the spring-low-water mark on an intertidal flat at the mouth of House Creek, Little Tybee Island, Georgia. Bags were harvested in May 14, 1996 with all clams per bag counted and 50 individuals measured for shell length.

Statistical Analysis

One-way Analysis of Variance (ANOVA) ($\alpha = 0.05$) and Tukey's Studentized Range Test (SRT) ($\alpha = 0.05$) using SAS for PC (SAS Institute Inc. 1989) were carried out in each study. All proportion survival data was arcsine square root transformed prior to statistical analysis.

RESULTS

Cage and Mesh Bag Stocking Density Study

Greater Atlantic surfclam survival ($p = 0.0040$) occurred in cages (77%) than in mesh bags (53%). No significant difference ($p = 0.1994$) in clam survival occurred among any cage treatments (Table 1); however, mean survival of clams ranged from 52% in cages stocked at 300 clams/m^2 to 87% in cages stocked at 500 clams/m^2. Significant differences ($p = 0.0258$) in clam survival occurred among the mesh bag treatments with survival ranging from 22% in densities of 100 to 73.5% at 500 clams/m^2. Although survival of clams in bags increased with increases in stocking densities (Table 1), clam survival at the 100 clams/m^2 stocking density was only significantly lower than that at 500 clams/m^2.

Significant differences in clam size occurred among stocking densities in both cages ($p < 0.0001$) and mesh bags ($p < 0.0001$; Table 1). In general and with the exception of 100 stocking density, mean clam size decreased with increases in stocking densities in cages, i.e., 200 clams/m^2 ($\bar{x}$ = 56.5 mm) = 300 clams/m^2 ($\bar{x}$ = 57.0 mm) > 100 clams/m^2 ($\bar{x}$ = 52.8 mm) > 400 clams/m^2 ($\bar{x}$ = 49.1 mm) = 500 clams/m^2 ($\bar{x}$ = 51.0 mm) > 600 clams/m^2 ($\bar{x}$ = 46.5 mm). In the mesh bags, clam size was significantly lower in the 100 clams/m^2 bags ($\bar{x}$ = 26.6 mm) which was greater than 300 ($\bar{x}$ = 29.4 mm) > 200 clams/m^2 ($\bar{x}$ = 32.9 mm) = 400 clams/m^2 ($\bar{x}$ = 32.8 mm) = 500 clams/m^2 ($\bar{x}$ = 34.6 mm). Overall in the mesh bags, clam size increased with increases in stocking density. Surfclams achieved a greater size in cages versus mesh bags regardless of stocking density. In cages, mean Atlantic surfclam size ranged from 46.5 mm at 600 clams/m^2 to 57 mm at 300 clams/m^2, whereas, in mesh bags mean clam size ranged from 26.6 mm in 100 clams/m^2 to 34.6 mm in 500 clams/m^2 treatments (Table 1).

Mesh Size Study

Growth and survival data of the Atlantic surfclam cultured in various mesh bag diameters are given in Table 2. ANOVA showed that no significant difference ($p = 0.0623$) in clam size occurred among treatments; however, Tukey's SRT showed that clams from the 12-mm mesh bags were smaller (26.1 mm) than those from the 3-mm (33.1 mm) and 6-mm (32.2 mm) mesh bags. The results of the 12-mm mesh bags are moot, as only two animals survived (0.3%). ANOVA of survival data showed significantly greater survival occurred for clams stocked in the 3-mm mesh bags (62%) versus the 6-mm mesh bags (19%).

DISCUSSION

Surfclams demonstrated greater growth and survival when cultured in bottom cages as compared to the mesh-bag culture technique. Surfclams grown in cages achieved approximately twice the size of those grown in mesh bags at equivalent stocking densities (Table 1). The lowest size of clams in cages (46.5 mm in 600 clams/m^2 treatments) were 34% larger than the greatest size of clams in the mesh bag (34.6 mm in 500 clams/m^2) treatment. Atlantic surfclams had 1.5 times higher survival rate in cages than in mesh bags (Table 1).

Surfclams grow slower in mesh bags than in cages. The reason for this is unknown, but restricted water flow within the bags and increased exposure to turbulence are two possible explanations. Because the bags are lying on the sediment, water flow does not pass through the bags as it does for a cage. Instead water flows over the top of the bags. The cage sides cause a baffling effect thereby allowing food particles to fall out of the water column and consequently being more readily available to the clams. The physical pressure of the bag lying on the clam may have prevented efficient siphoning by the clam and hence, resulted in reduced feeding capabilities. In addition, currents appear to effect the bags more than the cages in this study. Although a few cages exhibited

some wash-out of sediment, most mesh bag-lines were found twisted and in some cases completely relocated. Several times the lines had to be untangled and relaid. The physical movement of clams within bags by currents combined with the effects of increased densities resulting in a concentration of the clams into one end of the bag could retard growth. The effects of current on the bags may also explain why the higher bag stocking densities produced better clam growth and survival than that occurring in the lower density bags. The weight of the additional numbers of clams may provided a more stable environment within the bag.

In a similar study, northern quahogs, *Mercenaria mercenaria*, grew better in cages and in gravel filled trays than in the mesh-bag-line system (Walker 1997). Although growth was lower for northern quahogs cultured in mesh bags as compared to that for clams in cages or trays, survival of animals was found significantly higher in the mesh-bag treatment (Walker 1997). This was not the case for surfclams in this study. Atlantic surfclams in bags had 53% survival compared to 77% for those in cages. In most cases, greater growth and survival of surfclams occurred in bags with higher stocking densities. The increased biomass associated with higher densities may have provided a somewhat more stable environment consequently, the bags were not disturbed as much as less densely filled bags. During the northern quahog experiment at this same site (Walker 1997), bags were found filled with sediment at the end of that experiment; whereas, in this study, most bags were devoid of sediment.

The effects of stocking density on the growth of various bivalve species is well documented, whereby growth tends to be reduced

with increases in stocking density (Adams et al. 1994, Eldridge et al. 1979, Walker 1984, Goldberg 1989, Walker & Hurley 1995). Goldberg (1989) planted 15.7 mm Atlantic surfclams at 500, 1000, and 2000 clams/m^2 in bottom cages and after approximately four months, clams had grown to a mean size of 47.3 mm, 40.8 mm, and 32.0 mm L, respectively. In our study, 15.5 mm Atlantic surfclams planted in bottom cages at densities from 100 to 600 clams/m^2 showed significant decreases in growth between 200–300 and 400–500 clams/m^2 with slowest growth occurring at 600 clams/m^2 (Table 1). Interestingly, the lowest stocking density in bottom cages in our study (100 clams/m^2) yielded slower growth rates than the 200 and 300 clams/m^2 stocking densities, but had higher growth rates than did the 400 to 600 clams/m^2 stocking densities. Furthermore, the lowest stocking density of 100 clams/m^2 regardless of growout protocol yielded lower growth rates across both culture treatments compared to the 200 and 300 stocking densities (Table 1). The optimum stocking density for culturing Atlantic surfclams in Georgia to achieve maximum size is 300 clams/m^2; however, as discussed below, optimum stocking density for obtaining marketable size animals efficiently is 500 clams/m^2.

Aquaculture Recommendation

Aquaculture of Atlantic surfclams has excellent potential in coastal Georgia. Atlantic surfclams are easily spawned and reared under hatchery conditions. Seed can be grown in the hatchery to a field-planting size by mid-October, once ambient water temperatures decrease below 28°C. Ambient river temperatures in Georgia which may reach 31°C are lethal to the Atlantic surfclam, so seed must be reared in the hatchery at lower water temperatures throughout the summer months (Walker et al., 1997). Clams must be harvested by May to early June before ambient water temperatures reach 28°C. Atlantic surfclams are marketable within six months from planting. The results of this work show that cages can be seeded at different densities to produce an optimum sized clam (50 mm) for the lucrative steam or fried clam markets via a staggered crop method. Cages seeded at densities of 200 to 300 clams/m^2 can reach the targeted market size of 50 mm by March to April with cages seeded at 500 clams/m^2 achieving the same market size in May to June. Thus, by seeding at the optimum density for producing a maximum sized clam, the culturist can produce marketable clams early in the season. By seeding at 500 clams/m^2 for maximum production, clams will attain market size toward the end of the growing season (May to early June).

ACKNOWLEDGMENTS

The author thanks Capt. J. Whitted of the R/V SEA DAWG for his efforts in transporting cages and animals from the field. Dr. F. O'Biern, Mr. D. Hurley and Ms. D. Moroney are thanked for their help in deploying cages, bags and animals and in terminating the experiment.

COMPARISON OF RECRUITMENT FREQUENCY AND GROWTH OF SURFCLAMS, *SPISULA SOLIDISSIMA* (DILLWYN, 1817), IN DIFFERENT INNER-SHELF HABITATS OF NEW JERSEY

MARNITA M. CHINTALA[1,2] AND JUDITH P. GRASSLE[1]

[1]*Institute of Marine and Coastal Sciences, Rutgers, The State University of New Jersey, New Brunswick, New Jersey;* [2]*U.S. Environmental Protection Agency, NHEERL, Atlantic Ecology Division, Narragansett, Rhode Island*

ABSTRACT *Spisula solidissima* (Dillwyn, 1817) populations along the U.S. East Coast reflect episodic settlement and recruitment success. An analysis of growth bands in the shells of 1,005 surfclams collected from nine zones within 3 miles of the coast of New Jersey in 1993 revealed years of good recruitment, and allowed the construction of growth curves for each zone. The 1988 year class predominated in most areas, comprising 53.5% of all clams sampled, followed by the 1986 year class (8.3%), and the 1983 year class (5.0%). In the zones located farthest north, 3- to 5-year classes each represented at least 10% of the samples. All of the zones south of Barnegat Inlet were dominated by the 1988 year class, which accounted for 45% to 95% of the clams within these zones. The temporal patterns of recruitment across mile zones, depth gradients, bottom types, or catch densities did not appear to be significantly different. There was considerable variation among the growth curves for surfclams along the coast. An examination of the shell height at age 5 (H_5) for the 1988 year class in the northern and southern zones supports earlier findings that surfclams farther inshore grow more slowly and reach a smaller maximum size than clams farther offshore. The fact that the expected mean height at age one (H_1) for the 1988 year class was the same throughout all zones suggests a single, widespread settlement event along the coast in that year. An analysis of U.S. EPA surface and bottom temperature data (1979–1991) indicated that mean temperature for summer 1988 was lower than for all other years in the six northern zones, and was also relatively low in the three southern zones. Lower mean summer seawater temperatures are correlated with a higher frequency and persistence of coastal upwelling events, which in turn are associated with high larval abundances in the downwelling that immediately follows each upwelling. Thus, high recruitment may be the consequence of these hydrodynamic effects on larval supply, in addition to the effects of cool bottom temperatures in reducing predator impacts on recently settled surfclams.

KEY WORDS: surfclams, recruitment, growth, *Spisula solidissima*, New Jersey

INTRODUCTION

The surfclam, *Spisula solidissima* (Dillwyn, 1817), is one of the most abundant bivalves inhabiting eastern United States waters (Jones 1981a), and currently supports one of the largest shellfisheries on the east coast. It is found on the continental shelf in exploitable concentrations from the surf zone to depths of 50 m from Nova Scotia to North Carolina (Merrill & Ropes 1969, Abbott 1974, Wagner 1984, NEFSC 1998, NEFSC 2000), with lower densities offshore (Haskin 1978). In 1974, the highest concentration of surfclams in the New York Bight occurred off the southern coast of New Jersey in depths greater than 18 m (Garlo 1982), but in recent years the highest concentrations have occurred off northern New Jersey (NEFSC 1998, NEFSC 2000).

In 1977, approximately 80% of all U.S. clam products were from surfclams (Loesch & Ropes 1977, Wagner 1984). Surfclams have been heavily fished since the 1940s, and overfishing led to a decline in surfclam densities (Jones 1981a). Although *S. solidissima* can settle in very high numbers (e.g., 250,000 per m^2 at an inshore site in 1993, Weissberger 1998), most populations have nearly complete mortality by late summer and fall in many years (Haskin et al. 1979, Garlo 1982, Weissberger 1998). These mortalities have been attributed to hypoxia and anoxia, which destroyed up to 62% of the New Jersey surfclam resource in 1976 (Ropes et al. 1979, Garlo 1982), and to predation (Garlo 1982, Botton & Haskin 1984, Mackenzie et al. 1985, Weissberger 1998, Weissberger 1999). Weinberg (1999) has shown that although U.S. Exclusive Economic Zone (EEZ) populations off Delmarva and New Jersey had only 2- or 3-year classes in 1978 following the widespread hypoxia in 1976, additional year classes recruited in relatively low numbers throughout the next two decades.

The variability in successful recruitment of this species in inshore areas is due in large part to post-settlement predation (MacKenzie et al. 1985, Weissberger 1998). Previous research has shown differences in growth rates between inshore and offshore clams, with inshore clams growing more slowly, reaching a smaller maximum size, and having shorter life spans than offshore clams (Jones et al. 1978, Jones 1980, Ambrose et al. 1980). These growth differences have been attributed to density differences and differences in annual mean temperatures (Ambrose et al. 1980, Jones 1981b, Weinberg 1999). In the present study we examined only populations that had been previously described as inshore populations (Giust 1993). This research was part of an ongoing effort to determine where and when settlement and good growth occur off New Jersey. We are testing the hypothesis that there have been successful year classes of surfclams, other than the post-anoxia year classes, that have recruited off the coast of New Jersey to support the fishery.

MATERIALS AND METHODS

Stations Sampled

Surfclams were collected from 26 stations along the coast of New Jersey (Fig. 1). Two stations were located at the Rutgers University's Long Term Ecosystem Observatory site in 15 m depth (LEO-15) and the other 24 were a subset of 318 stations in a survey by the New Jersey Department of Environmental Protection (NJ DEP) in July and August 1993. The stations chosen by the NJ DEP were assigned using a stratified design (Giust 1993) based on previous annual surveys and were not randomly distributed in the zones, located 1, 2, and 3 miles off the NJ coast (Fig. 1). The 24 stations were chosen based on their geographic location and the probability of gaining a sufficient number of surfclams. Whenever possible, our stations were selected along a latitudinal line perpendicular to the shore.

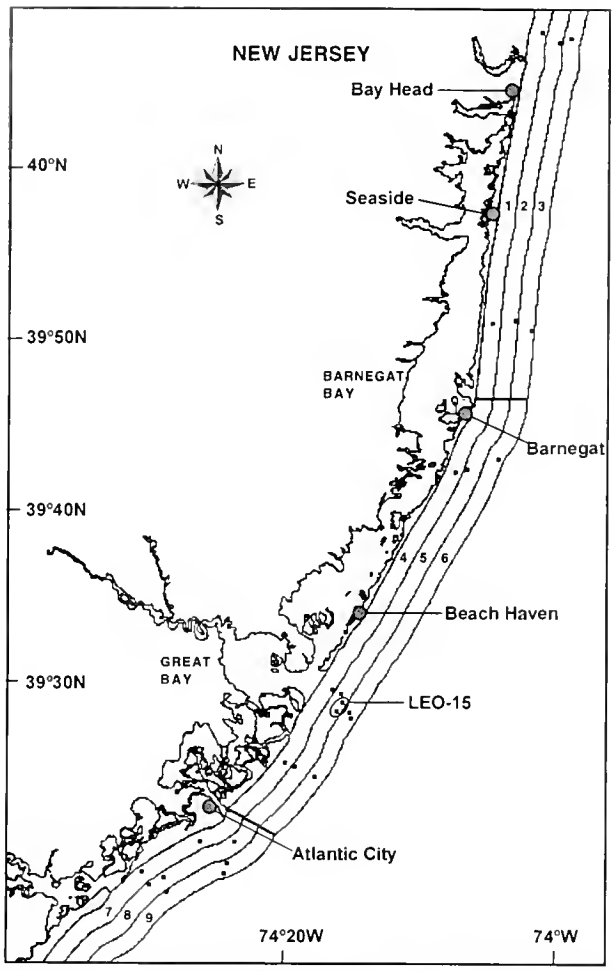

Figure 1. Coast of New Jersey indicating the stations where surfclams were sampled in 1993. Lines paralleling the coast delineate the 1-mile zones for NJ DEP sampling. Numbers indicate the zone delineations. Cities and towns indicate the origins of U.S. EPA weekly transects measuring surface and bottom temperature and oxygen concentration in May to September, 1979–1991.

Clams were collected by a commercial hydraulic clam dredge equipped with a 72-inch knife. The dredge floor was lined with Springfield fencing with 51-mm square mesh. Ring diameter in the metal bag at the cod end of the dredge was 72 mm (Giust 1993). The smallest clam that was caught with this dredge and measured was 33 mm in length. We followed the same assumptions as Weinberg (1999) in that clams smaller than this were completely missed during sampling and that other clams that could pass the ring size of the dredge were not sampled quantitatively. One tow was taken per station, and was assumed to randomly sample surfclams fully retained by the dredge in that area. Clams were haphazardly selected from a one-bushel subsample at each station (sample size ranged from 6–69). These surfclams were shucked on board and the shells were returned to the laboratory for age and growth determination. The data from the different stations were analyzed by zones as described below.

Recruitment and Growth Curve Determinations

The shells were cleaned and height was measured. Because the clams were large, they were not embedded prior to cutting and counting the growth lines (Jones, pers. comm.). For consistency, whenever possible, only the right valve was cut for age and growth determinations. On some occasions it was necessary to use the left valve when the right valve broke during sectioning. A single cut was made with a diamond saw from the umbo to the ventral margin along the axis of maximum height (Jones et al. 1978). The shell edge was polished on a lapidary wheel for 2 to 3 min until the edge was smooth. The dark internal growth lines were counted and used to back-calculate the year of settlement for each of the clams since Jones et al. (1978) have shown that the growth lines are annual.

The height at each age was measured directly from the dark, internal growth lines, which were traced from the chondrophore to the outer shell surface. The shell was examined under a dissecting microscope at 60× or 120× (objective and eyepiece magnification) and the exit point of the growth line was marked with a pencil. The straight-line distance from the umbo to the point of exit of each growth line at the shell's outer surface (Jones et al. 1978) was measured to the nearest 0.1 mm with calipers. In this way, a series of height-at-age measurements were obtained from each individual.

Analysis of Data

Data were analyzed as in Cerrato and Keith (1992). A von Bertalanffy curve was fit to the shell height vs. age data by nonlinear least-squares analysis using SAS for all clams measured in each of the zones (Cerrato 1990). The algebraic form of the von Bertalanffy curve used in these analyses was

$$h = H_1 + (H_{max} - H_1)(1 - x^{t-1}), \quad (1)$$

where h is the shell height at age t, H_1 is the expected mean height at age 1, H_{max} is the asymptotic maximum size, and x is the expected fractional reduction in annual increment growth (Cerrato & Keith 1992). Parameter estimates were determined for H_1, H_{max}, and x. The growth parameter, k, which is a measure of how fast a population reaches its maximum size, was calculated as follows:

$$x = e^{-k}. \quad (2)$$

The 1988 year class was the predominant year class in most of the samples. Therefore, we ran a separate analysis on the representatives of that year class. Because individuals in this year class had not yet approached their asymptotic growth stage, the algebraic form of the von Bertalanffy equation used for this analysis was (Cerrato & Keith 1992)

$$h = H_1 + (H_5 - H_1)(1 - x^{t-1})/(1 - x^4), \quad (3)$$

where H_5 is the height at age 5 and the other parameters are the same as in equation (1). Parameter estimates for H_1, H_5, and x were determined and analyzed.

Analyses of the parameter estimates from the nonlinear regression were done with likelihood ratio tests, and 95% confidence intervals were generated by projecting the likelihood regions onto the appropriate axes (Cerrato 1990, Cerrato & Keith 1992). Data were analyzed by zone, with each zone containing two to five stations. The experiment-wise error rate was 0.05, and the per comparison rate was 0.05/p, with p = 36, the number of comparisons.

Temperature and Dissolved Oxygen Data

Temperature and dissolved oxygen data, taken from 1 and 3 miles off the New Jersey coast for years 1979 to 1991, were

obtained from the U.S. EPA (1994). Surface (1 m below surface) and bottom (1 m above bottom) data were collected as part of the U.S. EPA helicopter water quality sample collection for the New York Bight area. Sampling occurred weekly during the summer each year from approximately mid-May to late September. The weekly values were averaged to get a mean surface and bottom temperature for each station and station values within a zone were averaged. The sampling entailed nine transects extending east from the NJ coast, with five stations in each transect. The only transects used were those from Bayhead (corresponding to zones 1 and 3), Seaside (zones 1 and 3), Barnegat (zones 4 and 6), Beach Haven (zones 4 and 6), Atlantic City (between zones 4 and 7, and 6 and 9), and Strathmere (zones 7 and 9) (Fig. 1; Chintala 1997).

RESULTS

Recruitment History of S. solidissima

The 1988 year class was predominant in the samples (53.5% of all clams sampled), followed by the 1986 year class (8.3%), and the 1983 year class (5.0%). Zones 1, 2, and 3 had surfclams from many different year classes (Fig. 2, A–C). Zone 1, the zone located furthest north and within 1 mile of the shore, was the only zone where the 1983 year class was the most abundant (Fig. 2A). The 1986, 1987, and 1989 year classes were also well represented (>10%) in this sample. Zone 2, between miles 1 and 2, was dominated by five year classes, 1982, 1983, 1986, 1987, and 1988 (Fig. 2B). The northern zone farthest offshore, zone 3, was more clearly dominated by the 1986 year class (Fig. 2C), but several other year classes were represented in the sample.

Most of the other zones (4–8), were dominated by the 1988 year class (Fig. 2, D–H). This year class accounted for 45% to 95% of the clams within these zones. Although the 1988 year class was the most prevalent in zone 9 (33%), there were also a large number of 1976 and 1977 year class clams in these samples (29.6% and 18.5%, respectively; Fig. 2I). Recruitment across mile zones was similar since the same age-class pattern was seen in zones 1 through 3, zones 4 through 6, and zones 7 through 9 within each mile; however, towards the south and farther offshore, the number of clams in the post-anoxia year classes (1976–1978) became more prominent (Fig. 2I). The northern stations appeared to be represented by a wider range of year classes than farther south (Fig. 2). South of Barnegat Bay, the samples appeared to be overwhelmingly dominated by the 1988 year class.

Growth Curves of S. solidissima

The likelihood ratio tests indicated that the von Bertalanffy growth curves were the same for zones 1 and 4 and for zones 8 and 9. For all the other pairwise zone combinations, the growth curves were significantly different from one another (Table 1). The growth in the first 3 to 4 y of life was similar for the nine zones (Fig. 3). The growth curves up to age 5 for zones 5 through 8 were lower and more variable than those from other zones, probably due to the dominance of the 1988 year class (Fig. 3).

The expected mean height at age 1 (H_1) was the same for zones 1 and 4 through 9 (Fig. 4A). Clams in zones 2 and 3 were significantly smaller at age 1 than those in the other zones. The expected maximum height (H_{max}) varied among zones and had smaller confidence intervals than H_1 (Fig. 4B). Again, H_{max} in zones 2 and 3 were not significantly different from one another, but were greater

TABLE 1.

Likelihood ratio tests comparing the von Bertalanffy growth parameters among zones (1–9) off the New Jersey coast. The test statistic is $-2\log(\Lambda)$ where Λ is the likelihood ratio. Significant outcomes are underlined. The maximum likelihood estimates under the null hypotheses were calculated by iteratively reweighted least squares due to heteroscedasticity in the error variances between stations. The experiment-wise error rate for each hypothesis was 0.05, and the per comparison error rate was $\alpha = 0.05/p$, where p is the total number of pairwise comparisons (based on the Bonferroni inequality). A paired comparison was significant if $-2\log(\Lambda) > n\log[1 + (q/\nu)F^{\alpha}_{q,\nu}]$, where q is the number of parameters being compared, n is the total sample size, $\nu = n - 6$, and $F^{\alpha}_{q,\nu}$ is the upper α percentile point of the F distribution with q and ν degrees of freedom. (Cerrato 1990, Cerrato & Keith 1992).

than all but zone 6. Zones 1, 4, 7, and 8 were not significantly different. Likewise, zones 5, 8, and 9 were not significantly different from each other, and zones 1 and 5 were the same (Table 1). The largest H_{max} was in zone 6, one of the offshore zones. The clams with the smallest H_{max} were found in zones 1, 4, and 7 within 1 mile of the New Jersey coast (Fig. 4B).

The growth parameter k ranged from 0.164 to 0.396 (Fig. 5). Zone 6, which had the highest H_{max}, also had the lowest k, while zone 8 had the highest k. The statistical analysis showed that the k value for zones 1, 3, 4, and 9 were not significantly different from one another, nor were zones 2, 3, and 5 different from each other.

Growth Curves of 1988 Year Class of S. solidissima

Testing if all the von Bertalanffy parameters were equal for all zones showed the following homogeneous groups: zones 1 and 4; zones 2, 3, and 9; zones 1 and 5; and zones 5 and 7 (Fig. 6; Table 1). The analysis of H_1 showed that there were no significant differences among the zones (Fig. 7A; Table 1). The largest clams at age one were in zones 5 and 6. The greatest variability in H_1 was in zones 1 through 3, zones that also had the lowest number of 1988 year class clams (Fig. 7A). The estimate of the height at age 5 showed that clams from zones 2, 3, and 9 were similar and were also the largest (Fig. 7B). The smallest clams were in zones 5, 6, and 7, with only zones 5 and 7 not significantly different from each other (Table 1). Zones 1 and 4 were the same as were zones 1 and 8 (Fig. 7B).

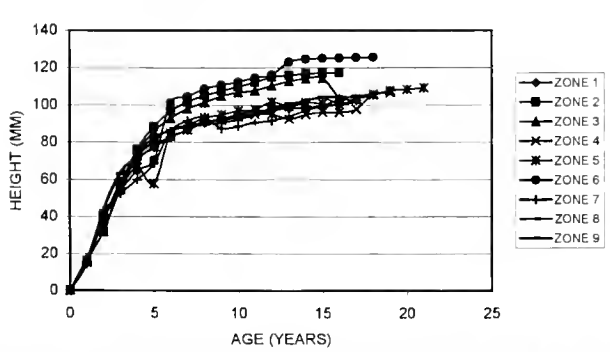

Figure 3. Mean height (millimeters) at each age for all clams collected at each of the stations in the nine zones off the coast of New Jersey.

Temperature and Dissolved Oxygen Data

Only the summer means (from mid-May to late September) for the surface and bottom temperatures and dissolved oxygen measurements for the stations that corresponded to clam sampling stations were examined. The data for stations in each of the inshore zones (1, 4, and 7) and the offshore zones (3, 6, and 9) were averaged. In zones 1 and 3, mean summer surface and bottom temperatures tracked each other closely from 1979 to 1991, with surface temperatures being 4°C to 5°C above bottom temperatures in every year (Chintala 1997). In zones 1, 3, 4, and 6 there were lower average temperatures in 1988 than in all other years (Fig. 8). At the southern border of zones 4 and 6, and in zones 7 and 9, temperatures were low in 1988, but not uniquely so, during this 13-year period (Fig. 8). Dissolved oxygen data showed very little variation at any of the sites, varying by less than 3 mg/L throughout the 13 y, and there was no evidence of widespread, long-lasting hypoxia (see Chintala 1997 for complete temperature and dissolved oxygen data).

DISCUSSION

S. solidissima commonly experiences episodic recruitment (Loesch & Ropes 1977) and age-class dominance in dense populations (Murawski & Serchuk 1989). Since the anoxic event off the New Jersey coast in 1976 that killed 62% of the New Jersey surfclam resource in one area (Garlo 1982), it had been thought that the fishery was supported predominantly by the 1976 and

1977 year classes (Murawski & Serchuk 1989). These year classes survived, most likely because of the anoxia-related mortality of the main predators of juvenile *S. solidissima*, including the crab, *Ovalipes ocellatus*, and the starfish, *Asterias forbesi* (Garlo 1982, MacKenzie et al. 1985). Cerrato and Keith (1992) found that in 1988, the surfclam populations in estuarine waters off Long Island Sound, which were not affected by the hypoxia further south, were instead dominated by the 1983 and 1984 year classes.

Previously, it had been thought that there was little or no recruitment to the fishery inshore or offshore subsequent to the 1976

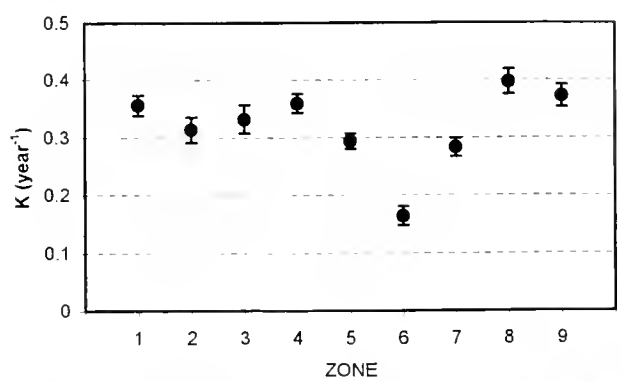

Figure 5. The time each clam population takes to reach maximum size (k) for all clams collected in each zone. Values were determined by Eq. 2 in the text. Bars indicate the 95% confidence intervals for each estimate.

and 1977 cohorts (NEFSC 1989, Murawski & Serchuk 1989). In the area designated as Northern New Jersey (area from the New York/New Jersey border south to 39°10′ or 30°30′ latitude, depending on distance offshore (Serchuk et al. 1979)), NMFS determined in a 1992 EEZ assessment study that there was no evidence of any substantial recruitment since 1976-1977. However, in southern New Jersey, they determined that there was some recruitment into the fishery between the years 1986 and 1992 (Weinberg

1993). The 1988 year class, which dominated the central and southern regions of our sampling regime, falls within this time frame. These results suggest that a significant settlement event occurred off southern New Jersey in both the inshore and EEZ populations during this time. Recent data have shown that the EEZ surfclam fishery has indeed been supported by multiple year classes throughout the 1980s and 1990s (Weinberg 1999). In an area offshore from our sampling stations in NJ, it appeared that after the 1976 hypoxia event, there were several years when surfclam recruitment was relatively high, followed by several years of relatively low recruitment. A 1997 assessment showed that the 1976 and 1977 cohorts were then only a small component of the population, which was represented by at least 19 year classes (Weinberg 1999).

The results from our inshore collections suggest that a new year class (1988) had recruited to the fishery, at least off the central and southern New Jersey coasts. Six of the nine zones sampled were dominated by this year class, and in some zones, such as 5, 7, and 8, it was the only major year class present. The only substantial remnant of the post-anoxia population (1976 and 1977 year classes) was seen in zone 9.

The NJ DEP has reported that the inshore surfclam population structure in 1992 was still dominated by the 1976 and pre-1976 year classes that survived the anoxic conditions (Giust 1993), the average shell length of the surfclams being 94.1 mm. To compare our results with those from the NJ DEP reports, we converted the surfclam shell heights to lengths using a height:length ratio for each station. The mean length of the dominant 1988 year class in our samples at age 4 (corresponding to 1992) varied between 60 and 80 mm, depending on the station, but it was difficult to compare these values with the overall mean in the NJ DEP study since their clams were not aged.

The issue of when the dark growth bands used in age determinations are laid down in the shell has been extensively discussed by Jones et al. (1983), who used oxygen and carbon stable isotopic analyses in a single surfclam shell taken from 9 to 10 m depth off the Barnegat Light (at the southern border of zone 1 in the present study) to examine the correlation between shell increments and monthly average sea surface temperatures. He concluded that in this inshore environment, shell growth is most rapid in spring and early summer, slows in late summer and fall, and is extremely slow or nonexistent in the winter. This agrees well with our own observations at the LEO-15 site on Beach Haven Ridge (zone 5 in this study; Weissberger 1998, Ma 1999, Grassle unpubl. data). Past research has suggested that the age bands were laid down annually in surfclams (Jones et al. 1978, Jones et al. 1983). One notable feature of Jones (1983) study was the large shell length (~56 mm) at age 1 of the individual surfclam that was studied. Jones (1983) noted that the values of $\delta\ ^{18}O$ predicted from the monthly sea surface temperatures and the measured oxygen isotope values in the first growth increment agreed well except during the months of January through March, and that it indeed represented only 1 year's growth. If settlement of this individual had occurred in the early summer, as is likely off Barnegat Light, and the first clearly visible growth line was laid down in the winter of the following year, the first growth increment may, in fact, have represented growth over 16 to 18 mo, making the length at "age 1" less anomalous. In the present study, the expected mean shell heights at age 1 (H_1) were considerably lower (ranging from 8.0 mm in zone 3 to 17.5 mm in zone 9, corresponding to shell lengths

of ~10.3 and 22.0 mm, respectively), than the previous the shell height at age one (56 mm) of the individual in Jones (1983) study. The first band is often incomplete and faint in surfclams, and these lines may have consistently been missed or ignored in earlier studies, resulting in apparently large shell heights at age one (Jones 1983, Ropes 1985). Some error could have been introduced in the determination of the first age band, but the most likely factor to affect H_1 would be the time of settlement of the larvae. Larvae that settle later in the year would be expected to have a smaller H_1. One of the most striking characteristics of the 1988 year class is the fact that H_1 was the same in all the zones. This suggests a single, widespread settlement event within 3 miles of the coast in 1988.

It has also been suggested previously that growth lines might be laid down at the time of spawning (Jones 1980). There does not seem to be any positive evidence for this in surfclams living off New Jersey, and contrary to previous suggestions that surfclams first reach sexual maturity at age 2 (Ropes 1979), inshore surfclams as young as 3 mo of age and 5 mm in shell length were found to be sexually mature (Chintala & Grassle 1995). It is likely that inshore and offshore surfclams spawn at different times each year, with the inshore clams spawning as soon as bottom temperatures increase above 12°C to 13°C in the late spring or early summer. The offshore clams probably do not spawn until bottom temperatures reach this level as a consequence of the breakdown of the thermocline in the early fall, or because of storm mixing (Haskin et al. 1979, Weissberger 1998). Benthic community studies at LEO-15 indicate that surfclam settlement occurs not only in the early summer, but at low levels in the fall (e.g., October and December of 1993; Weissberger 1998), and molecular identifications of bivalve larvae indicate the presence of surfclam larvae in the water column in winter (December and February of 1995/1996; Gregg, Tucker & Grassle, unpubl. data). Thus, it seems likely that the larvae produced by spring/early summer spawning of inshore surfclams settle in early summer, while those produced in the fall may settle in the winter and grow very little prior to the following summer. As a result, the first winter growth line may therefore only be visible in the shells of clams that settle in the summer.

A number of hypotheses to explain slower growth (and therefore a decrease in von Bertalanffy parameters) from New Jersey and Delmarva surfclam populations in the EEZ were put forward by Weinberg and Helser (1996) and Weinberg (1999). Among these were the rapid population increase following the 1976 anoxia event, which might have increased intraspecific competition; commercial size-selective harvesting; and the use of hydraulic dredges that damage clams, expose them to predators, resuspend bottom material, and potentially decrease food quality. Although these hypotheses were for surfclam growth differences from offshore regions that do not overlap with our sampling area, each of these hypotheses could also explain the differences in growth curves in the inshore New Jersey regions that we sampled, since the 1976 anoxic event also affected many inshore regions of New Jersey, and hydraulic clam dredges are used to harvest clams within the 3-mile New Jersey coastal zone.

Results suggest uniformly slower growth along the northern coast of New Jersey within 1 mile of shore, and off southern New Jersey 2 to 3 miles offshore. This slower growth could be a lingering effect of competition from the 1976 and 1977 year classes, even though those year classes are now essentially gone from the populations except in zone 9. The explanation for this growth differential is complex since there is a spatial and temporal component to the variability. In addition, the smallest maximum heights were from surfclams within 1 mile of shore (zones 1, 4, and 7), while the largest maximum heights were in populations 2 to 3 miles offshore (zones 2, 3, and 6). Also, the lowest k (how fast the population reaches maximum size) was in zone 6, suggesting a less rapid reduction in annual growth with age, while the highest k was in zones 1, 4, 8, and 9, suggesting a rapid reduction in annual growth with age. These findings do not support previous results that inshore clams always grow more slowly and reach a smaller maximum size than those farther offshore (Jones et al. 1978, Ambrose et al. 1980, Jones 1980, Wagner 1984, Cerrato & Keith 1992).

There were also many differences in the expected mean height at age 5 (H_5) among the zones, suggesting that environmental or growth conditions are different among zones. The fastest growth for the 1988 year class was in zones 2, 3, and 9, while the slowest growth appeared to be in zones 5, 6, and 7. The H_5 for this 1988 year class in zones 1 and 7 were less than in zones 3 and 9, suggesting that in the northern and southern zones the surfclams furthest offshore had grown faster and reached a larger size than those inshore. This pattern was not supported in the central zones (zones 4–6). These H_5 differences could be related to density, since Cerrato and Keith (1992) found that H_5 decreased significantly with surfclam density in the waters off Long Island. Density had no effect on the H_1 (0–300 clams per m^2), but a significant decrease in H_5 was found with densities >100 per m^2. In the present study, some of the largest clams were found in zones 2 and 3, and likewise, the highest H_5 for the 1988 year class clams was in these zones. In a study off the Delmarva Peninsula in an area closed to commercial harvesting from 1980 to 1991, Weinberg (1998) found that the intensity of apparent competition among surfclams was greatest in areas of the highest density. This competition was evident in a strong negative relationship between mean surfclam length and density of clams aged 5 to 12 y. Unfortunately, in the inshore New Jersey areas where we sampled, intense harvesting could have obscured the relationship between density and growth rate by disturbance from the hydraulic clam dredges and removal of large numbers of clams from an area in a short period of time (Weinberg 1998).

Reasons for the success of the 1988 year class are likely to be multiple and complex. The stations were located within 3 miles of the New Jersey coast. There did not appear to be a pattern of settlement within the mile zones. There did appear to be a latitudinal gradient, however, with the northern regions being dominated by numerous year classes and the more southern zones being dominated overwhelmingly by the 1988 year class. Gradients in age-structure have been identified for other surfclam populations along the east coast. Cerrato and Keith (1992) reported that east of Fire Island Inlet, New York, on the south shore of Long Island, the surfclam population was characterized by a wide range of ages with no evidence of age class dominance, but in Long Island Sound and at Long Beach, one or two age classes dominated and there were few or no clams >8 y old.

Temperature records from the U.S. EPA (1994) indicate that the mean summer surface temperatures in 1988 were the lowest in 13 y over much of the study area (ranging from 17°C to 18°C), and mean bottom temperatures were 12°C to 15°C in zones 1 through 6. These low mean summer bottom and surface temperatures likely reflect the frequency and persistence of near-coastal

summer upwelling events. The differences among the zones alongshore in different years are not surprising considering the way in which the upwelling nodes along the New Jersey coast are distributed (Glenn et al. 1996). Downwelling that follows the upwelling events in the vicinity of the LEO-15 site in zone 5 have been shown to be associated with relatively brief pulses of very high concentrations of *S. solidissima* larvae (Ma 1997), and subsequent larval settlement (Ma unpubl. data). Thus, it is not surprising to find a correlation between a measure of upwelling (low mean summer surface or bottom temperature) and surfclam year class strength. Good growth years and good recruitment years for *S. solidissima* have previously been associated with cool rather than warm years (Jones 1980). Generally, cool summers and frequent inner-shelf upwelling events may be associated not only with high larval settlement, but also with reduced mortality due to changes in predator abundance or predator activity (Weissberger 1998).

ACKNOWLEDGMENTS

We would like to thank Lori Guist Mayer, Jeff Normand, and the rest of the field crew for their assistance in collecting surfclams. Doug Jones and Michael Kennish provided tremendous assistance in cutting and aging the surfclam shells. Robert Cerrato was invaluable in sharing statistical analyses. Lastly, we thank Steve Schimmel, Sam Wainright, Peter Morin, Gary Taghon, Robert Cerrato, Jim Weinberg, and two anonymous reviewers for their editorial comments. This is contribution No. 2001-11 from the Institute of Marine and Coastal Sciences at Rutgers University and Contribution No. AED-01-017 from the United States Environmental Protection Agency. Although the writing of this manuscript was partially funded by the U.S. Environmental Protection Agency, it does not necessarily reflect the views of the Agency. A portion of this project was supported under Rutgers/CMER project 93-05 titled "Surfclam Recruitment."

CHROMOSOMAL MAPPING OF THE VERTEBRATE TELOMERIC SEQUENCE (TTAGGG)N IN FOUR BIVALVE MOLLUSCS BY FLUORESCENCE IN SITU HYBRIDIZATION

YONGPING WANG[1,2] AND XIMING GUO[1,*]

[1]*Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, New Jersey 08349;* [2]*Experimental Marine Biology Laboratory, Institute of Oceanology, Chinese Academy of Sciences, 7 Nanhai Road, Qingdao, Shandong 266071, People's Republic of China*

ABSTRACT The presence and chromosomal location of the vertebrate telomeric sequence (TTAGGG)n was studied in four bivalve molluscs: the eastern oyster, *Crassostrea virginica* Gmelin; the mangrove oyster, *Crassostrea rhizophorae* Guilding; the hard clam, *Mercenaria mercenaria* Linnaeus; and the dwarf surfclam, *Mulinia lateralis* Say, using fluorescence *in situ* hybridization (FISH). Metaphase chromosomes were prepared from embryos, and the vertebrate telomeric probe was labeled with digoxigenin and detected with fluorescein labeled anti-digoxigenin antibodies. Positive FISH signals were detected in all four species. Signals were restricted to telomeric regions of all chromosomes, and no interstitial sites were observed. Results of this and previous studies suggest that the vertebrate sequence is likely the telomeric sequence for all bivalve molluscs, which so far are the only invertebrates showing the vertebrate lineage in telomeric DNA.

KEY WORDS: FISH, chromosome, telomeric sequence, mapping, evolution, mollusca

INTRODUCTION

Telomeres, the specialized protein-DNA structures at ends of linear chromosomes, are essential for the stability of all eukaryotic chromosomes. Telomeres protect chromosomes from DNA degradation and end-to-end fusion, and may play important roles in aging and oncogenesis (Blackburn 1991, Harley et al. 1990, Hastie et al. 1990). In most organisms, telomeric DNA consists of tandem repeats of very simple sequences (6–10 bp), which are often conserved across taxa. All vertebrates studied so far have the same telomeric sequence, (TTAGGG)n (Meyne et al. 1989, Zakian 1995). The vertebrate sequence is shared by some other organisms such as *Trypanosoma* protozoa, several slime molds and fungi (Zakian 1995). In invertebrates, telomeric sequences are not extensively studied, but available data show more diversity. Most insects studied have a telomeric sequence of (TTAGG)n, while *Drosophila* flies and some other insects do not have either the insect or the vertebrate telomeric sequence (Okazaki et al., 1993). Telomeric sequence in *Drosophila* flies consists of transposable elements, not simple repeats. Nematodes have a telomeric sequence of (TTAGGC)n (Zakian 1995). Two groups of ciliates, *Tetrahymena* and *Oxytricha*, have different telomeric sequences of (TTGGGG)n and (TTTTGGGG)n, respectively.

Telomeric sequences in molluscs are largely unknown. Only four bivalves have been studied so far, and interestingly all four bivalves contain the vertebrate sequence, (TTAGGG)n, making them the only invertebrates sharing the vertebrate sequence to date. The presence of the vertebrate sequence has been demonstrated in the freshwater clam *Corbicultina leana* (Okazaki et al. 1993) and bay scallop *Argopecten irradians* (Estabrooks 1999) by Southern blot, and in the Pacific oyster *Crassostrea gigas* (Guo & Allen 1997) and the common clam *Donax trunculus* (Gonzáles-Tizón et al. 1998) by fluorescence *in situ* hybridization (FISH). FISH is widely used to assign genes and DNA fragments to chromosomes or subchromosomal regions (Lichter & Cremer 1992). In FISH, DNA fragments are labeled with reporter molecules, such as biotin and digoxigenin, through nick-translation or PCR-incorporation of labeled nucleotides. The labeled probes are denatured and hybridized to denatured metaphase chromosomes. After washing under desired stringencies, hybridized probes are detected with fluorochrome-conjugated reporter binding molecules such as avidin (for biotin) and specific antibodies. Hybridization signals are directly visualized under fluorescence microscope.

To examine if the vertebrate telomeric sequence is shared by a variety of bivalves, we studied the presence and location of this sequence by FISH in four more species: the eastern oyster *Crassostrea virginica* Gmelin, the mangrove oyster *Crassostrea rhizophorae* Guilding, the hard clam *Mercenaria mercenaria* Linnaeus, and the dwarf surfclam *Mulinia lateralis* Say. Here we report the presence of the vertebrate sequence in telomeric regions of all chromosomes in all four species. Our results along with previous studies suggest that the vertebrate telomere sequence, (TTAGGG)n, may be the telomeric sequence for all bivalve molluscs, which at present are the only invertebrates showing the vertebrate lineage in telomeric DNA.

MATERIALS AND METHODS

The eastern oysters used for this study were from a Rutgers University strain, NEH, which has been selected for MSX-resistance for about 40 years and for Dermo-resistance for about 10 years. MSX and Dermo are two diseases caused by the parasites *Haplosporidium nelsoni* and *Perkinsus marinus*, respectively. The mangrove oysters were from a F1 Caribbean population produced and maintained at the Harbor Branch Oceanographic Institute, Florida. The hard clams were obtained from a clam culture company, Biosphere Inc., New Jersey. The dwarf surfclams were collected from beaches of Rhode Island in the fall 2000.

Chromosome Preparation

Metaphase chromosomes were obtained from cultured embryos in all four species, according to the methods described by Guo and Allen (1997). For oysters and the dwarf surfclam, gametes were

*Corresponding author. E-mail: xguo@hsrl.rutgers.edu

collected by dissecting gonads. For the hard clam, females and males were induced to spawn by thermal simulation.

Eggs were collected by passing through a 60-μm nytex screen to remove large tissue debris and rinsed on a 25-μm screen. Sperm suspension was filtered through a 25-μm screen. Eggs from several (3–6) females and sperm from several males were collected and pooled. Eggs were resuspended in 23–25°C seawater (at about 1000/ml) and fertilized by adding sperm suspension to a final density of about 5–10 sperm per egg. Embryos were cultured in filtered and UV-treated seawater at 23°C. At 6–8 hours post fertilization (about 64-cell stage), embryo suspension was concentrated on a 25-μm screen and harvested into a 15-ml tube: 0.2 ml of embryos per 10 ml seawater. Embryos were treated with 0.005% colchicine in seawater for 10–15 min. Embryos were pelleted by centrifugation at the end of the treatment. Colchicine was replaced by 0.075 M KCl, and the hypotonic treatment lasted for 10–15 minutes. Embryos were then fixed with freshly made Carnoy's fixative, 1:3(v:v) acetic acid and methanol. Fixative was changed twice before storing at 4–7°C.

Chromosome spreads were made by dropping embryo/cell suspension onto clean glass slides and flooding the slides with 2–3 drops of 1:1 methanol and acetic acid. Slides were air-dried at an angle of 45°C. Slides were stored at −20°C until FISH analysis.

In situ Hybridization

FISH was conducted according to a protocol from Oncor Inc, modified and described in Guo and Allen (1997). Prior to hybridization, slides were pretreated in ×2 SSC (0.3 M sodium chloride and 0.03 M sodium citrate, pH = 7.0) at 37°C for 30 minutes. Slides were then dehydrated in 70%, 80% and 95% ethanol for 2 min each and air-dried. Chromosomes on the slides were denatured in 70% formamide in 2× SSC at 72°C for 2 min and dehydrated in a series (70%, 80% and 95%) of ice-cold ethanol. Slides were air-dried, and areas containing chromosome spreads were marked.

A commercially available all-human telomere probe, (TTAGGG)n labeled with digoxigenin and supplied in hybridization solution (Oncor), was used for this study. A 10-μl aliquot of probe was denatured at 72°C for 5 min, immediately cooled on ice and applied to the marked area on each denatured slide. A cover glass was applied and sealed with rubber cement. Slides were then incubated overnight in a humidified chamber at 37°C for hybridization. After hybridization, slides were washed for 5 min in 2× SSC at 72°C, and for three times, 2 min each, in 1× phosphate buffered detergent (PBD, provided by Oncor) at room temperature. The stringency of the post-hybridization wash was increased to 0.5× SSC to test hybridization strength. Negative treatment controls were included and made by replacing the probe with equal amounts of hybridization solution.

Hybridization was detected with fluorescein-labeled anti-digoxigenin antibodies (Ventana). Sixty μl of detection reagent were applied to each slide, covered with a plastic coverslip and incubated at 37°C for 5 min. Detection reagent was washed three times with 1× PBD. Slides were counterstained with 18 μl of propidium iodide/antifade and analyzed under a Nikon epi-fluorescence microscope with PI and PI/FITC dual-pass filters. Metaphase images and FISH signals were captured with a 3CCD camera and analyzed using the Image-Pro Plus software.

RESULTS

Preparations from early embryos provided sufficient metaphases for FISH analysis, and most contained elongated chromosomes. All metaphases analyzed in the eastern and mangrove oysters had 20 chromosomes as expected (Longwell et al. 1967, Rodriguez-Romero et al. 1979). Metaphases from the two clam species had 38 chromosomes as previously reported (Wada et al. 1990, Menzel & Menzel 1965). All chromosomes of dwarf-surf clam are acrocentric.

FISH with human telomeric probe (TTAGGG)n produced strong hybridization signals on interphase nuclei and metaphase chromosomes in all four species examined. Analysis of metaphase chromosomes showed that FISH signals were located at telomeric regions of all chromosomes in all four species: the eastern oyster (Fig. 1A), the mangrove oyster (Fig. 1B), the hard clam (Fig. 1C) and the dwarf surfclam (Fig. 1D). The signals were clear and strong in all four species even under high wash stringency (0.5× SSC). Most images were collected after high stringency wash, although results from low stringency (2× SSC) wash were almost identical, or occasionally stronger. All signals were limited to telomeric regions, and no minor or weak interstitial sites were detected even under low wash stringency.

FISH signals were present at telomeres of two sister-chromatids of each chromosome, although occasionally the signal intensity varied. On some chromosomes, the signal on one chromatid was stronger than that on the other chromatid. In some cases, signal intensity varied somewhat among chromosomes. From several metaphases analyzed, there was no apparent difference in the size or intensity of signals among the four species. No signals were observed in the treatment controls.

DISCUSSION

Results of this study clearly demonstrate that the vertebrate telomeric sequence (TTAGGG)n is present in telomeric regions of all chromosomes in all four bivalve species examined. The strong FISH signals obtained under high stringencies are an indication of complete homology between the probe and targeted sequence, rather than cross-hybridization to related sequences. In a *Corbulina* clam and the bay scallop, the (TTAGGG)n sequence hybridized to genomic DNA in Southern blot, while other telomeric sequences, such as the insect (TTAGG)n, the nematode (TTAGGC)n and the protozoan (TTGGGG)n, did not (Okazaki et al. 1993, Estabrooks 1999). The lack of cross-hybridization among different (although similar) telomeric sequences has also been demonstrated in many other species (Okazaki et al. 1993, Meyne et al. 1995). Other telomeric sequences were not included in this study, because they are not comparable with the vertebrate sequence in length and labeling. Nevertheless, it would be helpful to test all telomeric sequences in molluscs by FISH in the future.

Chromosomal location of the vertebrate sequence has not been studied by FISH in the *Corbiculina* clam and bay scallop. In the Pacific oyster and a *Donax* clam, the vertebrate sequence has been located to telomeric regions of all chromosomes (Guo & Allen 1997, Gonzáles-Tizón et al. 1998). Including the four species examined here, all eight bivalve molluscs studied so far shared the vertebrate telomeric sequence. Those findings lead us to believe that the vertebrate sequence, (TTAGGG)n, may be the telomeric sequence for most, if not, all bivalve molluscs. This finding is interesting, because at present, bivalve molluscs are the only invertebrate group showing the vertebrate lineage in telomeric DNA. Nematodes and most insects have different telomeric sequences (Zakian 1995). However, telomeric sequences in most invertebrates have not been studied, and it is possible that the vertebrate sequence is shared by other invertebrates.

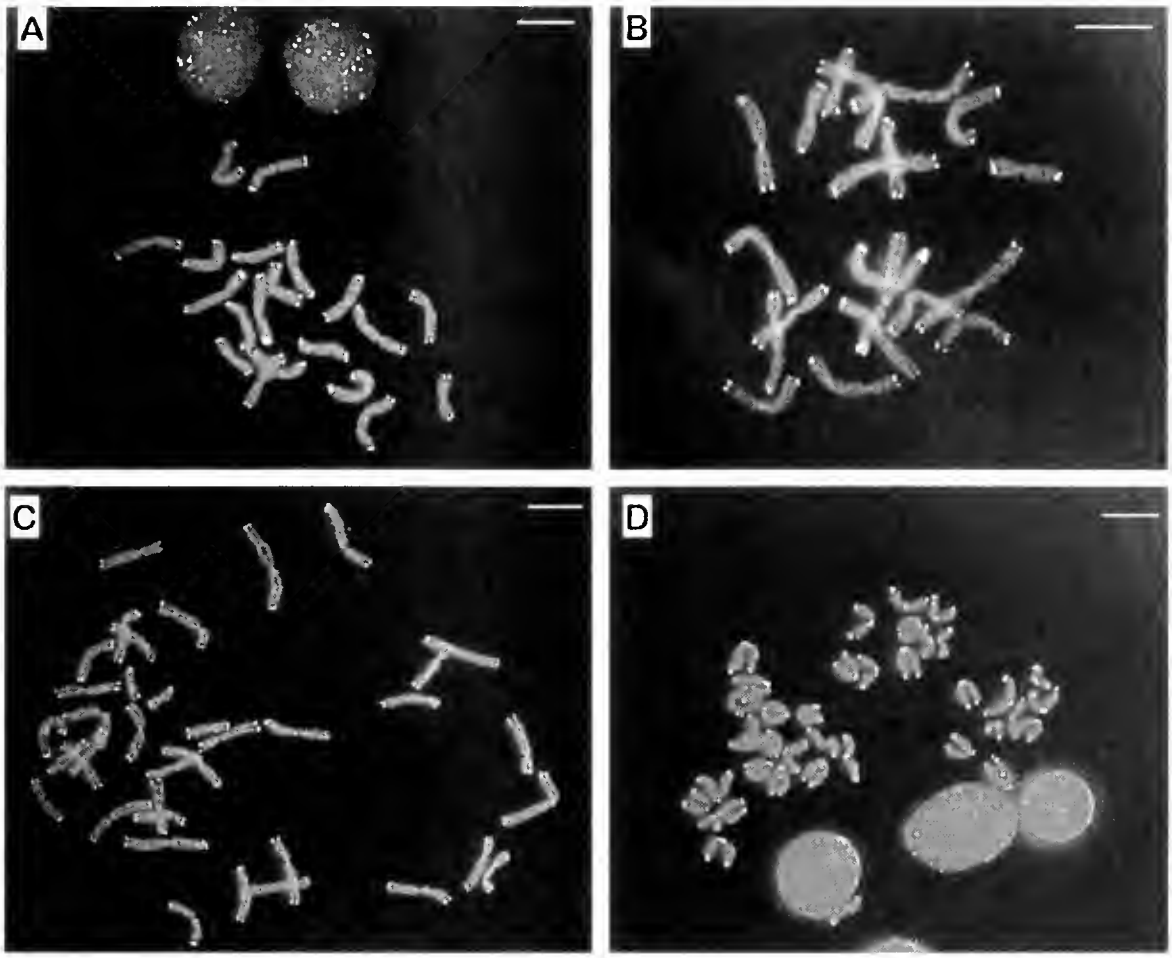

Figure 1. Fluorescence *in situ* hybridization of the vertebrate telomeric sequence (TTAGGG)n to telomeres of all chromosomes in four bivalve molluscs: A, the eastern oyster, *Crassostrea virginica*; B, the mangrove oyster, *Crassostrea rhizophorae*; C, the hard clam, *Mercenaria mercenaria*; and D, the dwarf surfclam, *Mulinia lateralis*. Bar = 5 μm.

It should be pointed out that telomeric DNA in most organisms is more complex than just repeats of one simple sequence. Besides the dominant simple sequence, minor simple repeats and moderate repetitive sequences may occur in telomeric regions (Zakian 1995, Meyne et al. 1995). The complete understanding of bivalve telomeric DNA requires cloning and sequencing of telomeric regions. The vertebrate sequence used in this study can be useful as a probe for cloning studies in bivalves.

Telomeric sequences have been found at interstitial sites in many organisms (Zakian 1995). In this study, all FISH signals were restricted to telomeric regions of chromosomes, and no interstitial sites were detected even under low stringency conditions. No interstitial sites were observed in the Pacific oyster and *Donax* clam (Guo & Allen 1997, Gonzáles-Tizón et al. 1998). The lack of interstitial sites for telomeric sequence may be an indication of limited karyotypic rearrangement through evolution. Karyotypes of *Crassostrea* oysters are highly conserved, and all species studied so far had a diploid number of 20 chromosomes, which are similar in morphology (Nakamura 1985, Xu et al. 2001). It is possible that interstitial sequences are present, but too short to be detected by FISH. The occasionally different signal intensities among some chromosomes and between chromatids may be due to random variations in hybridization condition, or may reflect true differences in target sequence size.

In conclusion, this study provides further evidence that the vertebrate telomeric sequence, (TTAGGG)n, is the telomeric sequence for bivalve molluscs. Studies on additional species are needed to test this hypothesis. It would be interesting to determine if other molluscan groups such as gastropods and cephalopods, also share the vertebrate telomeric sequence. The vertebrate telomeric probe and FISH analysis can be useful in studies on telomeric changes in molluscan development and aging (Harley et al. 1990, Estabrooks 1999).

ACKNOWLEDGMENT

The authors thank Dr. John Scarpa for providing mangrove oysters and Dr. Timothy Scott for providing dwarf surfclams. ENHANCEMENT EFFORTS ON STATE TIDELANDS BY THE WDFW INTERTIDAL SHELLFISH ENHANCEMENT PROJECT. Amilee Caffey, Brady Blake, and **Walt Cooke,** Washington Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, Brinnon WA 98320.

Due to an increasing demand for clam and oyster resources on public tidelands in Washington, the Washington Department of Fish and Wildlife (WDFW) developed the Intertidal Shellfish Enhancement Project in 1988. The goal of this project is to increase recreational opportunities by way of planting clam and oyster seed, as well as harvestable size oysters, onto public tidelands. Species targeted in the past have been Pacific oysters, geoduck and Manila clams. In the last few years, research has been conducted on culturing and enhancing native species such as butter, native littleneck clams and cockles. Enhancement efforts occur throughout Puget Sound. Creel surveys and population assessments of targeted clam species are conducted each year by WDFW and tribal staff. This information is passed to the Intertidal Enhancement Project and beaches are seeded according to Intertidal Management plans and needs.

The Enhancement Project purchases Pacific oyster seed and harvestable size oysters to be planted by commercial growers as directed by WDFW staff. The Point Whitney Shellfish Hatchery provides geoduck and Manila clam seed. Research performed by the WDFW Shellfish Hatchery on native species of slams such as butter, littleneck clams and cockles, have provided the Enhancement Project with small groups of seed for test plots, which will, in turn, lead to large scale planting of native species in the future.

THE USE OF HIGH HYDROSTATIC PRESSURE FOR THE REDUCTION OF *VIBRIO PARAHAEMOLYTICUS* IN SHELL OYSTERS. H. Calik, M. T. Morrissey, P. Reno, R. Adams, and **H. An,** Oregon State University Seafood Laboratory, 2001 Marine Drive, Astoria, OR.

High Hydrostatic Pressure (HHP) Technology has shown good potential pathogen reduction. The effect of HHP treatment on pure Vp culture was tested. Clinical and environmental strains of Vp were acquired from FDA was tested. Both clinical and environmental Vp strains were treated with HHP at different settings (1–10 min at 35K psi; 1–5 min at 40K psi; 30–120 s at 45K psi; 10–50 s at 50K psi). Total Vp was enumerated before and after HHP treatment to determine survival.

Additional tests were performed to determine if Vp in shell-oysters responds to HHP treatment differently than Vp in pure culture. After the inoculation of the same clinical and environmental Vp strains, oysters were treated with HHP at the same time and pressure settings.

Results showed that Vp is susceptible to HHP in both pure culture and shell-oyster treatments. The optimum conditions for reducing Vp counts from 109 cfu/ml to 101 cfu/ml was achieved at 50K psi in 30 seconds. At 35K psi, >10 min were required to reduce the count to 101 cfu/ml Vp survival.

HHP treatment was successful in reducing Vp counts. Vp in oysters and pure Vp culture responded similarly to HHP treatments. No resistance variation to HHP was detected between clinical and environmental Vp strains. HHP can be a viable means to reduce the Vp counts in oysters.

THE ROLES OF ENVIRONMENTAL STRESSORS AND CULTURE METHODS ON THE SUMMER MORTALITY OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS*. Daniel Cheney, Ralph Elston, Brian MacDonald, Kendra Kinnan, and **Andy Suhrbier,** Pacific Shellfish Institute, 120 State Ave NE #142, Olympia, WA 98501.

During the late summer to early fall period, Pacific oysters cultured on the west coast of the United States and elsewhere may experience high levels of mortality. In the 1960's to 80's, this condition was subject to intensive investigation focusing on broad areas of disease pathology, genetics, physiology and the environment. Results of these studies were largely inconclusive, or pointed to a poorly defined etiology. Although several factors, such as a bacterial and herpes-like virus infections could be linked to certain mortality events, no clear picture emerged.

Recent studies in Puget Sound, Washington USA and Tomales Bay, California USA center on the influence of multiple stressors and their affects on oyster survival, physiology and pathology. The goal of this research is to identify possible modifications in culture practices, brood stock selection or grow-out location to increase survival of Pacific oysters.

Field observations indicate oysters are subject to extreme variations in a number of parameters during intertidal cycles. Annual or seasonal variations in those parameters and culture practices appear to play a major role in oyster survival. An increased rate of oyster mortality and modified physiological response appears to be strongly correlated with both elevated temperatures and extended periods of depressed DO. A long period of neap tides with low and slack water during the evening was observed to result in daily and successive reductions in DO to levels ranging from 0.5 and 2 mg/L. The DO reductions are sometimes coupled with heavy macroalgae blooms and high phytoplankton densities. This and other work indicate oyster summer mortality rates are also strongly influenced by ploidy and broodstock origin/stock selection. These observations have renewed interest in testing selected stocks with reduced rates of summer mortality, which still retaining desirable characteristics of good growth and meat yield.

IMPLEMENTING A STUDY TO DETERMINE THE VALUE OF MOLLUSCAN SHELLFISH CULTURE AREAS AS FISH HABITAT IN WEST COAST ESTUARIES. **Brett Dumbauld,** Washington State Department of Fish and Wildlife, P.O. Box 190, Ocean Park, WA, 98640, **David Armstrong, Curtis Roegner, Kristine Feldman, Libby Loggerwell**, School of Fisheries, Box 355020, University of Washington, Seattle, Washington 98195, and **Steven Rumrill**, South Slough National Estuarine Research Reserve, P.O. Box 5417, Charleston, Oregon 97420.

The ecological role of bivalve molluscs in estuarine systems has recently been recognized in other areas including Europe and eastern North America where studies have been completed and in some cases shellfish restoration efforts initiated. Comparable studies are lacking however from estuaries on the West Coast, where bivalve (particularly oyster and clam) aquaculture often dominates the intertidal landscape. Due to increasing interest, especially with regard to the potential impacts of oyster aquaculture activities on juvenile salmonids (driven by the listing of several stocks under the Endangered Species Act), we are initiating a study designed to quantify both adverse, but also beneficial impacts of shellfish farming on selected estuarine fauna and flora. We will focus our initial efforts on oyster ground culture and on eelgrass as benthic habitats given the extent and previously documented value of these habitats respectively. Field and laboratory objectives include: 1) utilizing remote sensing and ground-truthing to document annual variability in eelgrass cover in oyster culture and eelgrass meadows in Willapa and Coos Bay estuaries; 2) compare species diversity, density and biomass in culture areas as well as eelgrass meadows; 3) conduct field experiments to examine the impacts of various culture activities on eelgrass and associated infaunal and epifaunal communities; and 4) conduct surveys of fish utilization in oyster beds and eelgrass meadows. Finally, we hope to prepare guidelines to assist both shellfish farmers and estuarine managers in avoiding and/or reducing adverse impacts on estuarine habitat while maximizing the potential beneficial impacts of aquaculture activities.

COMPARISON OF THE FIELD PERFORMANCES OF THE "100% OR NATURAL" TRIPLOID PACIFIC OYSTER *CRASSOSTREA GIGAS* WITH CHEMICAL TRIPLOIDS AND DIPLOIDS. **Benoit Endeline**, Taylor Resources INC, Whiskey Creek Shellfish Hatchery, 2975 Netarts Bay Road W., Tillamook OR 97141.

For about 3 years, the Whiskey Creek Shellfish Hatchery has been producing commercially a new kind of triploid Pacific Oysters (*Crassostrea gigas*) called "Natural" or "100%" triploid, made from the cross between regular diploids and tetraploids. The first advantage is that these "natural" triploids are always 100 percent triploid as verified by flow cytometry, insuring a high quality product for the customers. Hatchery seed was deployed in grow-out bags at two different locations for a 26-month study to examine the growth performance (length, whole weight, meat weight) and gonadal development of the natural triploids, chemical triploids and diploids. The "natural" triploid outperformed both diploids and chemical triploids on most of the characteristics studied. The final length was increased by 7 to 9% in the natural triploids compared to the diploids, the whole weight improved by 30 to 40% and the meat weight by 19% in the most productive area. The "natural" triploids outperformed as well the chemical triploids, with an increase of 7% in length, 15% in whole weight and 18% in meat weight in the most productive area. No histological differences were detected between "natural" and chemical triploids, but their gametogenesis was significantly reduced when compared to the diploids for the females and in a lower extend for the males.

MONITORING THE STATUS OF THE EUROPEAN GREEN CRAB INVASION IN WASHINGTON STATE COASTAL ESTUARIES. **Ronald Figlar-Barnes, Andrea Randall**, and **Brett Dumbauld**, Washington State Department of Fish and Wildlife, P.O. Box 190, Ocean Park, WA, 98640.

The European green crab (*Carcinus maenas*) was discovered on the West Coast of North America in 1989. A series of recruitment events led to expansion northward from San Francisco Bay including a particularly strong recruitment pulse which resulted in numerous crab being found in coastal estuaries from Oregon to British Columbia in 1998 and 1999. Washington State responded by establishing a statewide monitoring and control program for this invader in 1998.

Results from the monitoring effort to date in Willapa Bay and Grays Harbor, Washington suggest that the population in these estuaries is declining, despite evidence that local reproduction is potentially occurring. Average catch per unit trapping effort has declined markedly at a station located near the mouth of Willapa Bay. Mating couples and females with viable eggs were found during winter months and recruitment was documented in 1999, however larger crab representing the 1997/98 year class still dominate the catch. A volunteer trapping effort was successfully instigated along the western shore of Willapa Bay in 2000 and trapping methods continue to be refined as the primary control technique.

BIOLOGY AND FISHERIES POTENTIAL OF THE VARNISH CLAM, *NUTTALLIA OBSCURATA*, IN BRITISH COLUMBIA. **Graham E. Gillespie, Mia Parker,** and **Bill Merilees,** Fisheries and Oceans Canada, Pacific Biological Station, Nanaimo, BC. V9R 5K6.

Varnish clams, *Nuttallia obscurata*, have recently become established in British Columbia (BC), likely from introduction in ballast water. They are currently distributed from Cameleon Harbour (50°22′N) to at least Port Townsend (48°01′N) and on the west coast of Vancouver Island in Barkley and Clayoquot Sounds.

They have been reported from Oregon, but not from Grays Harbour or Willapa Bay, WA.

Varnish clams tend to be distributed at higher tidal elevations than Manila clams, prefer sand or gravel substrates and are often found in areas of freshwater outflows or seepage. When found with Manila clams, varnish clams tend to bury deeper in the substrate. Varnish clams use pedal feeding to augment suspension feeding and this, as well as their tendency to live deep in the substrate, may allow them to live at higher tidal elevations.

Varnish clams spawn in May in the western Pacific and histological examination of a BC sample taken late in March showed evidence that spawning had occurred. Varnish clams appear to grow at similar rates to Manila clams, reaching 38 mm in length in four years.

Varnish clams have potential as a commercial and recreational resources, as attractive clams with good meat-to-shell ratio and good shelf life. They are generally gritty and can recycle purged substrate from tanks. The soft-shelled nature of varnish clams present a problem due to breakage during harvest and transport.

Work is currently underway in BC to explore market potential and develop policy leading to commercial exploitation of varnish clams.

WHERE DOES THE GREEN CRAB FIT INTO THE HIERARCHY OF NATIVE CRAB PREDATORS? Laura Hauck, Sylvia Behrens Yamada, and **Sabre Mahaffy,** Zoology Department, Oregon State University, Corvallis, Oregon 97331-2914.

We compared prey size selection, prey consumption rates and mechanical advantage of the claw lever systems in the European green crab, *Carcinus maenas*, and five species of native crabs. Individual crabs were housed inside perforated plastic boxes in open seawater tanks at Hatfield Marine Science Center. We offered each crab 5 small (5–8 mm) 5 medium (8–11 mm) and 5 large (11–14 mm) snail (*Littorina sitkana*) per day and recorded their consumption rate.

Green crabs eat significantly more snails than the shore crabs *Hemigrapsus nudis* and *H. oregonesis* of similar size. While all 3 crabs prefer smaller snails, only green crabs eat the largest. They simply insert the slender tips of their minor claw into the snail's aperture and pull out the soft tissue.

Green crabs exhibit the same feeding rates as young Dungeness (*Cancer magister*) and red rock crabs (*C. productus*) of similar size. The mechanical advantage of claw lever systems are 0.25 for Dungeness, 0.28 for *Hemigrapsus nudis* and *H. oregonesis*, 0.36 for the master claws of male green crabs and 0.39 for red rock crabs. These comparisons suggest that the impact of green crabs on hard-shelled prey will be significantly higher than that of shore crabs and of the same order of magnitude as that of red rock crabs of similar size. This research was supported by Oregon Sea Grant.

IMPROVEMENTS OF YIELDS OF PACIFIC OYSTERS THROUGH GENETIC SELECTION. Chris Langdon, Dave Jacobson, Sean Matson, and **Ford Evans,** Coastal Oregon marine Experimental Station and Department of Fisheries and Wildlife, Oregon State University, Newport, Oregon, 97365.

Crosses were made in 1998 among nine families showing the highest yields (wet weight per bag) of 48 families planted at an intertidal site in Tomales Bay, California. The resulting full-sib families were plated at an intertidal site in Totten Inlet, Puget Sound, Washington, in 1998. In addition, full-sib families derived from crossing non-selected "wild" oysters were planted at this site as well as groups of oyster seed from various commercial sources. After about two years of growth, the families were harvested and the average yield (kg live weight) per bag determined for each family. The estimated realized heritability for yield was 0.42. Family yields varied greatly depending on the composition of the parental cross, with the average yield of inbred families being significantly less ($p = 0.0028$; Fisher's PLSD) than that of out-bred families from the selected broodstock; however, the average yield of the top nine families from the selected broodstock was 28% greater than that of industry oysters. Based on these results, it should be possible for industry to significantly improve oyster production by crossing specific selected families as part of a long-term breeding program. Inbreeding should be avoided as it results in significantly reduced yields.

SPATIAL STOCK STRUCTURE IN BRISTOL BAY (ALASKA) RED KING CRAB AND ITS INFLUENCE ON LONG-TERM RECRUITMENT TRENDS. Timothy Loher and **D. A. Armstrong,** University of Washington, School of Fisheries, Box 355020, Seattle, WA 98195.

The Bristol Bay red king crab (*Paralithodes camtschaticus*) stock once supported the most lucrative fishery in the world, but low catches over the last ~20 yrs have prompted fishery closures and a host of restrictive regulatory measures. However, these actions have had little effect on stock rebuilding, suggesting that factors outside the fishery may exert strong influence on population abundance.

We hypothesize that the population is regulated by the survivorship of early post-settlement stages that require complex substrates as nurseries, and that low recruitment levels are in part the result of climate forcing that has altered larval source-sink dynamics. We present evidence of alterations in broodstock distribution that occurred during the early 1980's, and changes in spatial recruitment patterns that roughly mimic the shifts in the adult population; the possible effects of the 1978 "climate regime shift" in initiating these changes will be discussed.

INTERTIDAL SPAWNING ECOLOGY OF THREE SPECIES OF MARINE FORAGE FISHES IN WASHINGTON STATE. Daniel E. Penttila, Washington Department of Fish and Wildlife, Marine Resources Div., LaConner, WA 98257.

The Pacific herring (*Clupea*), surf smelt (*Hypomesus*), and Pacific sand lance (*Ammodytes*) are common schooling forage fishes in the Puget Sound basin and coastal estuaries on Washington State. In spite of their pelaigic habitats, they are intimately associated with nearshore/intertidal benthic environments during their annual spawning activity. Herring use nearshore beds of eelgrass and marine algae for spawn deposition. Surf smelt and sand lance use upper intertidal sand-gravel beaches for spawning.

Marine forage fish spawning sites and seasons are unpredictable from year to year. Spawning commonly occurs for several months each year at any given spawning site. Preservation of all known spawning sites is considered critical for these species' long-term conservation.

In many areas, forage fish spawning sites and seasons overlap and coincide with shellfish aquaculture areas and commercial harvest activities. Means must be found to minimize disruption of forage fish spawning sites and seasons. Current environmental regulations consider all known marine forage fish spawning sites to be "habitats of special concern," and they are afforded "no net loss" protection from impacts of in-water human activities. Efforts are being made to inventory all Washington State shorelines for evidence of forage fish spawning activity.

PUGET SOUND DUNGENESS CRAB (*CANCER MAGISTER*) MOLTING PATTERNS. Donald Velasquez and **Steve Burton,** Washington Department of Fish and Wildlife, 16018 Mill Creek Blvd., Mill Creek, WA 98012-1296.

The Washington State Department of Fish and Wildlife and Treaty Tribes currently regulate the harvestable surplus of Dungeness crab in Puget Sound based on the following criteria: 1) male crab only, 2) a minimum size of male crab, and 3) avoiding pot harvest on soft male crab coming out of a major molt. With these conservation tools in place, the harvestable surplus is then allocated between the State and Treaty Tribes for a 50/50 split. State/tribal management plans set pot fishery seasons around the major molts and any deviation from these dates must be accompanied by tests to determine that 80% of the legal-sized, male crabs are in hardshell condition. Data from these shell condition tests indicates that the molting time period once considered appropriate for all of Puget Sound is not applicable for all of it's subareas. The results also suggest a trend in the molt timing from the northern regions to the southern regions.

ABSTRACT Gulfwatch is an international monitoring program that uses *Mytilus edulis* as the sentinel species for habitat exposure to toxic contaminants in the Gulf of Maine. Since 1991, the Gulfwatch program has measured the concentrations of 10 trace metals, 17 chlorinated pesticides, 24 polynuclear aromatic hydrocarbons (PAHs), and 24 polychlorinated biphenyl (PCB) congeners in mussel tissue from over 60 sites throughout the Gulf of Maine. In 1998, the Gulfwatch program included a more intensive survey of sites in New Hampshire. Of the 21 sites sampled in the Gulf in 1998, six sites were sampled in New Hampshire and the other 15 sites were in Nova Scotia, New Brunswick, Maine, and Massachusetts. Results for the Gulfwide program showed a southward trend of increasing concentrations for organic contaminants and Ag, Cr, and Pb, reflecting major local and regional pollution sources. The distribution of the remaining trace metals was more uniform, without obvious impacts from the more heavily urbanized areas of the southern gulf. At some sites there appears to be localized hot spots for a variety of contaminants. Gulfwide geometric mean (GM) concentrations were lower than GM +85% confidence level (CL) concentration for the NOAA National Status and Trends (NS&T) Mussel Watch program, except for Hg. Two sites had Pb concentrations that exceeded U.S. FDA guideline levels. While Hg concentrations did not exceed the U.S. FDA action concentration at any site, the NS&T GM +85% CL was exceeded at all 1998 Gulfwatch sites. The spatially intensive New Hampshire program has been useful in identifying local sources of contaminants and determining the significance of mussel exposure to oil from chronic discharges and larger spills. Similar to comparisons between Gulfwatch and NS&T data, interpretation of New Hampshire results benefit from comparisons to the greater Gulfwatch program. The Gulfwatch database provides a useful regional perspective to interpret the results from the New Hampshire program and for other localized studies. Gulfwatch provides unique, Gulfwide status and trend information and helps to focus efforts to reduce loading of contaminants such as Hg.

KEY WORDS: *Mytilus edulis*, toxic contaminants, Gulf of Maine, spatial trends

INTRODUCTION

The Gulf of Maine (GOM) extends from Cape Sable, Nova Scotia, through New Brunswick, Maine, and New Hampshire to Cape Cod, Massachusetts, and includes the Bay of Fundy and Georges Bank. The ecosystem is one of the world's most productive systems and supports a vast array of species, including some of great commercial importance. Commercial fisheries, including aquaculture, is its principal income-generating enterprise. Tourism is also a significant source of income to GOM coastal communities. Increases in coastal populations and industrial and residential development have contributed to the deteriorating quality of sections of the Gulf's coastal environment (Crawford & Sowles 1992, Dow & Braasch 1996). Despite efforts to improve pollution treatment, the result of increased human growth and activities is the steady input of toxic chemicals into estuarine and coastal environments. Many human-made chemicals can be bioaccumulated to concentrations significantly above ambient levels. Furthermore, some of these environmental contaminants may also be present at concentrations considered toxic to organisms, and thus induce adverse biological effects on productivity, reproduction, and survival of marine organisms and humans (Kawaguchi et al. 1999, Wells & Rolston 1991).

Monitoring programs may use a variety of organisms as indicators of environmental contamination. One organism that has been commonly employed and has proven useful for biomonitoring chemical contamination is *Mytilus edulis* L. (Sericano et al. 1995, Tripp & Farrington 1985). *M. edulis* and other bivalves have been used throughout the world as a measure of the spatial and temporal trends in habitat exposure to chemical contaminants. In addition, *M. edulis* has been successfully used as an indicator organism in environmental monitoring programs throughout the world to identify variation in chemical contaminants between sites, contributing to the understanding of trends in coastal contamination (NAS 1980, NOAA 1991, O'Connor 1992, O'Connor & Beliaeff 1995, Widdows et al. 1995, Cantillo 1998). The blue mussel is the indicator organism for the NOAA NS&T, Gulf of Maine Gulfwatch and New Hampshire Gulfwatch programs because of the following favorable characteristics: mussels are indigenous and abundant in many coastal areas, and are easy to collect and process; much is known about mussel biology and physiology; they are a commercially important food source; mussel contamination is a public health concern; and they are sedentary suspension-feeders that concentrate chemicals in tissue, making measurement of chemicals in mussel tissue an assessment of local biologically available contamination.

The overall objective of this paper is to introduce the Gulfwatch program to a wider audience of scientists concerned about the safe consumption of molluscan shellfish. The 1998 results are

presented to illustrate local, regional, and international implications and to address issues related to toxic contaminant pollution in the marine environment. Between 1991 and 1997 the Gulfwatch program measured the concentrations of trace metals, polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and chlorinated pesticides in mussel tissue at 56 sites throughout the GOM. In 1998, the Gulfwatch program was in the sixth year of a nine-year monitoring plan. By design of the Gulfwatch program, the 1998 sampling was the second sampling of sites previously sampled in 1995. These sites will be resampled in 2001 (Jones et al. 1998). Native mussels collected at 21 sites throughout the Gulf of Maine were analyzed for organic and inorganic contaminants (Crawford & Sowles 1992) to build on the program's Gulfwide assessment of long-term exposure to bioavailable contaminants. One location in each of the five jurisdictions served as a baseline station that has been resampled every year. The 1998 Gulfwatch program also included more spatially intensive sampling in New Brunswick.

MATERIALS AND METHODS

The 1998 Gulfwatch sample collection and analysis is the sixth year of the program's nine-year sampling design (Sowles et al. 1997). The 1998 sampling represents the third year of the second three-year cycle. As such, a subset of the total Gulfwide stations sampled in 1998 were previously sampled in 1995. Some select sites have been sampled each year since 1993 for more intensive temporal analysis of contaminant concentrations. The New Hampshire Gulfwatch program added six new sites in addition to six sites previously sampled under the Gulfwide Gulfwatch program; 1998 is the first year of sampling at three of the new sites in New Hampshire.

Locations for sites sampled as part of the Gulfwatch program prior to 1998 are shown in Figure 1. The stations sampled in 1998 are presented in Table 1 with reference to site numbers in Figure 1. The site list includes two New Brunswick sites located in St. John Harbor that were new in 1998. The six New Hampshire sites sampled in 1998 are shown in Figure 2, including three sites that had been previously sampled, NHLH, NHDP, and MECC, and three sites that were sampled for the first time: NHGP, NHSS, and NHNM. Clark Cove (MECC) in Portsmouth Harbor is a benchmark site that has been sampled each of the previous five years. Gulfwatch benchmark sites were established to enable trend analysis and were selected as sites considered to be important in each jurisdiction.

Field and Laboratory Procedures

Details regarding the mussel collection, measurement, and sample preparation are published in Sowles et al. (1997). All field sampling was conducted in the fall of 1998. No sampling occurred during or shortly after periods when storm water runoff and wave resuspension of bottom sediment could result in enhanced uptake and accumulation of sediment in the mussel gut, as previously reported (Chase et al. 1998). Mussels were collected from four discrete areas within a segment of the shoreline that is representative of local water quality. Using a wooden gauge or a ruler, 45–50 mussels of 50–60 mm shell length were collected. The mussels were cleaned of all sediment, epibiota, and other accretions in clean seawater from the collection site, placed in clean containers, then transported to the lab in coolers with ice packs. Mussels were not depurated prior to processing. Prior to shucking, mussels were thoroughly washed to minimize tissue contamination from any remaining surface debris.

Figure 1. Location of Gulfwatch stations in the Gulf of Maine.

In the laboratory, mussels were shucked directly into appropriately prepared Mason jars for metal and organic analysis, respectively (for details see Sowles et al. 1997). Composite samples (20 mussels/composite; four composites/station) were capped, labeled, and stored at −15° C for three to six months prior to analysis.

Analytical Procedures

Analytical procedures followed those reported for the previous years (Chase et al. 1998, Jones et al. 1998). Table 2 contains a summary of measured trace metal and organic compounds. Inorganic contaminants were analyzed at the State of Maine Health and Environmental Testing Laboratory (Augusta, ME). Analyses for mercury were done on a subsample of 1 to 2 g of wet tissue and measured by cold vapor atomic absorption on a Perkin Elmer Model 503 atomic absorption spectrometer. Analyses for all other metals were conducted on 5 to 10 g of wet tissue dried at 100°C. Zinc and iron were measured by flame atomic absorption using a Perkin Elmer Model 1100 atomic absorption spectrometer. All remaining metals (Ag, Al, Cd, Cr, Cu, Ni, and Pb) were analyzed using Zeeman background-corrected graphite furnace atomic absorption with a Varian Spectra AA 400. The analyte detection limits for the metals in μg/g dry weight (DW) are as follows: Ag, 0.1; Al, 4.0; Cd, 0.1; Cr, 0.2; Cu, 0.4; Fe, 4.0; Hg, 0.1; Ni, 0.4; Pb, 0.4; and Zn, 0.5.

Organic contaminants in mussel samples were analyzed at the Environment Canada, ECB Laboratory in Moncton, NB. The ana-

lyte detection limits ranged from 3.0 to 10 ng/g for aromatic hydrocarbons, from <1.0 to 2.0 ng/g for PCB congeners, and from <1.0 to 2.0 ng/g for chlorinated pesticides. Eighteen of the PCB congeners identified and quantified correspond to congeners analyzed by the National Oceanographic and Atmospheric Administration's (NOAA) National Status and Trends (NS&T) Program designated congeners. Other organic compounds selected for analysis are also generally consistent with NOAA National Status and Trends mussel monitoring (NOAA 1989).

A description of the full analytical protocol and accompanying performance-based QA/QC procedures are found in Sowles et al. (1997), and more comprehensively in Jones et al. (1998). Tissue samples were extracted by homogenization with an organic solvent and a drying agent. Solvent extracts were obtained by vacuum filtration, and biomatrix interference was separated from target analytes in extracts by size exclusion chromatography. Purified extracts were subjected to silica gel liquid chromatography, which provided a nonpolar PCB/chlorinated pesticides fraction and a polar chlorinated pesticide fraction. PCBs and pesticides were analyzed by high-resolution dual column gas chromatography/electron capture detection (HRGC/ECD). Following PCB and pesticide analysis, the two fractions were combined and the resulting extract was analyzed for aromatic hydrocarbons by high-resolution gas chromatography/mass spectrometry (HRGC/MS).

Standard laboratory procedures for metals incorporated method blanks, spike matrix samples, duplicate samples, surrogate addition, and standard oyster tissue (SRM 1566A). The method blanks were inserted as follows: three at the beginning of the run, one at the end, and six at various intervals during the run. Duplicate samples and matrix spike recoveries were conducted on 15% of the samples. The Moncton laboratory participated in the NIST Status and Trends Intercomparison Marine Sediment Exercise IV and Bivalve Homogenate Exercise. Internal quality control and method performance specifications are described in the Environment Canada Shellfish Surveillance Protocol (Sowles et al. 1997, Jones et al. 1998). The protocol includes mandatory QC measures with every sample batch including method blanks, spike matrix samples, duplicate samples, surrogate addition, and certified reference materials (SRM 1974a). The protocol specifies the performance criteria relevant to method accuracy, precision, and detection limits and data reporting requirements for the analysis of organic contaminants in shellfish samples.

Data Analysis

Total PAH ($\sum PAH_{24}$), total PCB ($\sum PCB_{24}$), and total pesticides ($\sum TPEST_{17}$) values were calculated from the sum of all individual compounds or congeners with values greater than the detection limit for the compound. Total DDT ($\sum DDT_6$) is the sum of o,p'-DDT and p,p'-DDT and homologues (o,p'-DDE, p,p'-DDE, o,p'-DDD, and p,p'-DDD). Several tissue samples for metals and organics were below the detection level. Variables in which all replicate measurements were below the detection limit were treated as zero and recorded as not detected (ND). However, if at least one of the replicates was greater than the detection limit, then the other replicates were recorded as 1/2 the detection limit.

All metal data, with the exception of Ag and Ni, were $\log_{10}$ transformed to correct for heterogeneity of variances, whereas all organic contaminant, Ag, and Ni data were $\log_{10}(x + 1)$ trans-

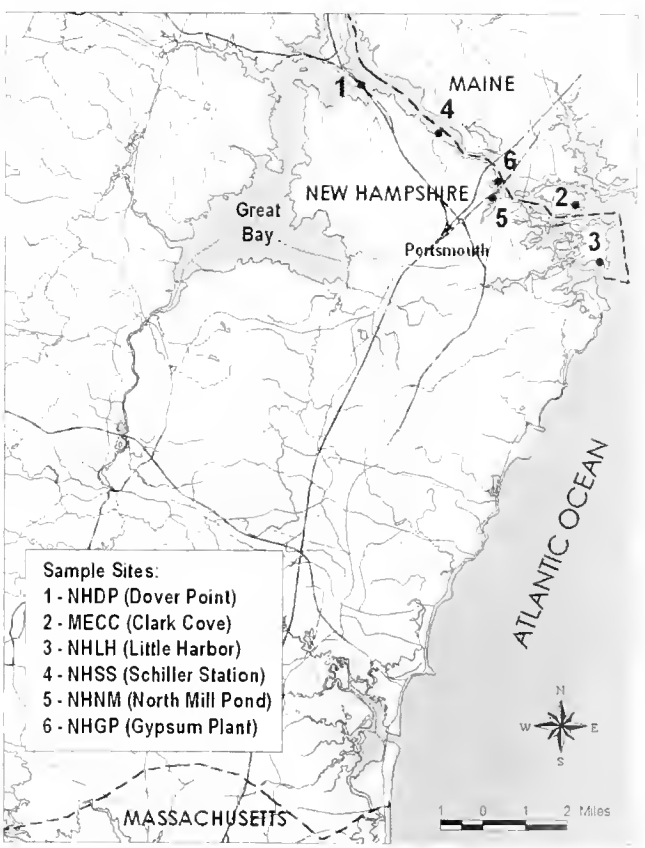

Figure 2. Location of 1998 Gulfwatch stations in New Hampshire.

formed. At each site, arithmetic means were used to summarize the results of replicate samples and are used in all subsequent tables and figures. In addition, geometric means were calculated for each metal and organic contaminant for comparison with other data sets. The confidence levels (CL) around the geometric mean were calculated as:

RESULTS AND DISCUSSION

Trace Metal Contaminants

Table 3 contains the metal concentrations (arithmetic mean ± SD, μg/g DW) for mussels from all site composite ($n = 4$) samples in 1998. Overall metal concentrations for indigenous mussels are given as geometric means and CI range (Table 3). Trace metals were detected at all sites except for Ag, which was below the detection limit (0.1 μg/g DW) at 10 of the 21 sites. No site had extremely high concentrations of any trace metal, although some sites like MAIH and most of the New Brunswick sites had elevated concentrations of some of the metals. Table 3 includes values for geometric means (GM) and GM +85% CL from the 1990 NS&T Mussel Watch data (O'Connor & Beliaeff 1995) for comparison. Using the NS&T GM +85%CL value as a reference for comparative purposes, two sites exceeded the Ag value, four sites exceeded the Cr value, six sites exceeded the Cu value, 17 sites exceeded the Hg value, two sites exceeded the Ni value, and six sites exceeded the Pb value out of the total of 21 sites. This suggests localized sources of these contaminants at those sites. However, for Cr, Cu, Pb, and especially Hg, more widespread elevated levels suggest possible regional sources of these contaminants.

The tissue analysis for Al and Fe is included to serve as an indication of the degree to which sediment contamination may be present in mussel tissue (i.e., the gut). The fact that four of the six New Brunswick sites had relatively high concentrations of Al and Fe suggests that the mussel tissue samples contained elevated levels of sediment. The presence of sediment in the mussels was suspected in samples having elevated concentrations of some metals (iron, aluminum, and associated metals) (Lobel et al. 1991, Robinson et al. 1993). Sites in the Bay of Fundy are dominated by extensive intertidal mudflats that can be subject to considerable resuspension during windy storm events.

The concentrations of most metals were relatively evenly distributed around the Gulf of Maine (Table 3). There were no apparent spatial trends; however, an occasional hot spot of elevated concentrations was observed. Figure 3 shows the concentrations of Ag, Pb, and Hg measured in the tissue of *M. edulis* at the 1998 sampling stations. The order in which sites are presented is from Cape Cod Bay, up along the coasts of New Hampshire and Maine, into the Bay of Fundy, and along the western shore of Nova Scotia.

Silver concentrations ranged from below the detection limit (0.1 μg/g DW) to 1.82 ± 0.20 (NBCG) and showed strong geographical hot spots of elevated concentrations in areas in each jurisdiction except New Hampshire along the Gulf of Maine (Fig. 3). The highest concentrations were observed in Massachusetts from Boston Harbor south to Sandwich and in New Brunswick around St. John Harbor. Elevated silver exposure concentrations have been shown to coincide with regions receiving municipal sewage (Sanudo-Wilhelmy & Flegal 1992, ten Brink et al. 1996). Because of silver's use in the photographic and jewelry industries, the coastal waters of Massachusetts are up to 1,000 times more concentrated in Ag than in other Gulf of Maine waters (Krahforst & Wallace 1996). The high levels observed at MASN, which is in an area with no known significant source of municipal waste, may

be a function of transport and deposition of sewage-derived particles (Bothner et al. 1993) that are sequestered in Cape Cod Bay and accumulated by mussels.

The concentration of lead ranged from a value of 0.58 ± 0.12 μg/g DW at two New Brunswick sites (NBNR and NBCH) to 26 ± 13 μg/g DW at Boston Inner Harbor (MAIH) (Table 3, Fig. 3). Lead levels at Boothbay Harbor, ME (MEBB) were also much higher than most other sites. Sediment particles containing Pb may be transported to Boothbay Harbor from the Kennebec-Androscoggin watershed (Larsen & Gaudette 1995). Lead concentrations were generally higher in the southwestern areas compared to the northern and eastern sites (Fig. 3). Mean concentrations of Pb in mussels from coastal regions generally range from 1 to 16 μg/g DW (Fowler 1990). All six of the NH sites sampled in 1998 exceed the Maine reference concentration (ME-RM; Sowles 1993) of 2.6 ± 1.1 μg/g DW, but no site exceeded the Maine high value (ME-HV) (6.00 μg/g DW). MAIH is located in a highly urbanized harbor and subjected to heavy industry, marine transport activities, and municipal waste discharges. Elevated lead in the New Hampshire sites may be related to the close proximity of the sites to the Portsmouth Naval Shipyard where waste plating sludge and lead batteries, respectively, were disposed and stored (NCCOSC 1997). The potential for the shipyard to be a source of lead to estuarine biota was demonstrated in July 1999 when significant amounts of soil from a contaminated site at the Shipyard, containing as much as 14.2 mg Pb/g soil DW, was discovered to be eroding into the Piscataqua River (Cohen 2000). Mussels collected from sites in close proximity to the eroding soil contained Pb concentrations as high as 199 μg/g DW.

The concentration of mercury in mussel tissue ranged from a value of 0.11 μg/g DW at NBLN to 1.08 ± 0.10 μg/g DW at NHSS (Table 3, Fig. 3). Mercury exceeded the NS&T GM +85% CL of 0.24 μg/g DW at 17 of the 21 sites. The New Hampshire sites are markedly higher than sites in other jurisdictions. There are several known historical mercury sources in the New Hampshire Seacoast, including some that are suspected to be related to the Portsmouth Naval Shipyard (NCCOSC 1997) and, especially, the PSNH Schiller Station (NHSS) on the Piscataqua River, where mercury steam was used from 1950 to 1968 (Nelson 1986). Analysis of the mussel tissue concentrations of Hg revealed that there was a significant difference in Hg concentrations between NHSS and all other New Hampshire sites except NHLH. Mean values of Hg in *Mytilus* spp. from coastal regions worldwide range from 0.1 to 0.4 μg/g DW (Kennish 1997), but can be much higher in areas like the southwest Pacific, where sites average as much as 2.7 μg Hg/g DW (Fowler 1990). In a review of the first five years of the Gulfwatch program, tissue concentrations of Hg were discussed as being unusually high and a possible concern (Jones et al. 1998).

Recent studies have shown that a mercury problem exists in freshwater systems of the northeast United States and maritime provinces of Canada (Welch 1994, DiFranco et al. 1995, Evers et al. 1996). About 47% of mercury deposition in the region originates from sources within the region, 30% originates from U.S. sources outside the region, and 23% originates from the global atmospheric reservoir (NESCAUM 1998). On June 8, 1998, the New England governors and eastern Canadian premiers agreed to cut regional mercury emissions from power plants, incinerators, and other sources in half by the year 2003. However, until recently few large coastal systems have been known to be impacted by Hg pollution. Atmospheric mercury deposition measurements made at New Castle, NH, at the mouth of Portsmouth Harbor, showed ~8 ng/m^2 total mercury was deposited during 1998 (MDN, unpub-

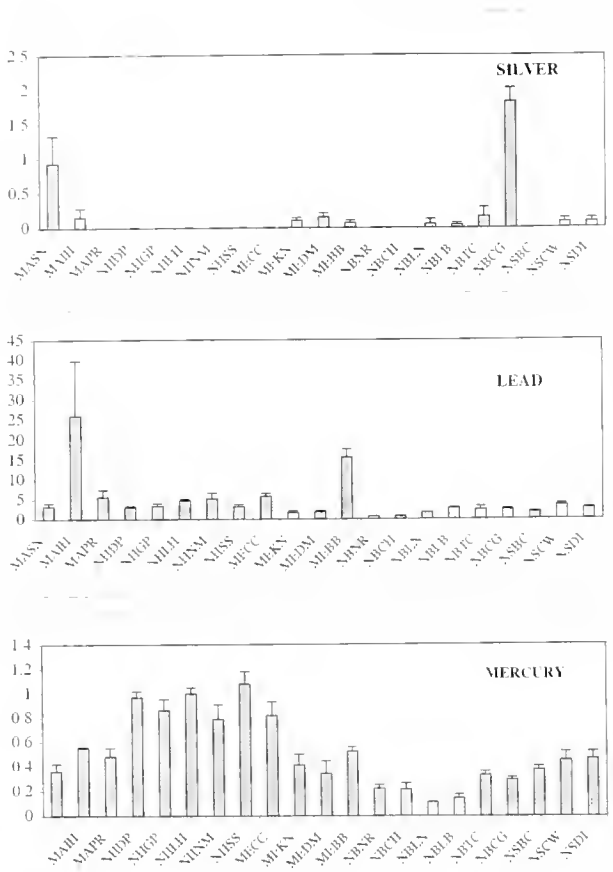

Figure 3. Distribution of silver, lead, and mercury tissue concentrations (arithmetic mean ± SD, µg/g dry weight) in mussels at all Gulfwatch stations in 1998.

lished). The New Castle site, along with two other Maine coastal sites in Casco Bay and Acadia National Park, showed somewhat elevated total mercury atmospheric deposition compared to nearby, upstream inland sites. Other areas in the Gulf of Maine have elevated (5–20 µg/g) sediment mercury concentrations (ten Brink et al. 1997), including the Penobscot River near Orrington, where permitted and accidental discharges from the Holtra-Chem facility have resulted in sediments having much higher (>100 µg/g) Hg concentrations (MEDEP, unpublished). Thus, data on mussel tissue mercury levels may have added importance in assessing current contamination problems and the effects of discharge reduction efforts related to Hg in the future.

Organic Contaminants

The total concentration of detectable polynuclear aromatic hydrocarbons (ΣPAH_{24}), polychlorinated biphenyls (ΣPCB_{24}), and organochlorine pesticides ($\Sigma TPEST_{17}$) measured in mussel tissue samples of indigenous mussels are presented in Table 4. Individual analyte concentrations of each compound class are not shown. In 1998, as in previous reports (Sowles et al. 1996, Chase et al. 1998, Jones et al. 1998), ΣDDT_6 and its degenerative metabolites were the main contributors to total detectable pesticides (data not shown). Analytes within each category of organic contaminant were detected at most sites, except for ΣPAH_{24} at MEDM and ΣPCB_{24} at NBCH, NSBC, and NSCW. There were much wider ranges in concentrations of organic compared to trace metal contaminants. None of the Gulfwatch sites had organic contaminant concentrations that exceeded any human health criteria. For example, the U.S. FDA Action Limit for PCB is 2 µg/g DW (USFDA 1990), and the concentration for the highest Gulfwatch site was 0.74 µg/g DW at MAIH, which is well below this limit.

A clear pattern of higher concentrations in the southwestern Gulf compared to the northeastern Gulf is apparent for all three types of organic contaminants (Table 4). This pattern can be seen in Figure 4, which shows the concentrations of ΣPAH_{24} and ΣPCB_{24} measured in *M. edulis* tissue from the 1998 sites, presented from south to north. The mean of the ΣPAH_{24} concentrations ranged from not detected (ND) at MEDM to 3,330 ng/g DW at MAIH. Mean concentrations of ΣPAH_{24} at all but a few of the Maine and New Brunswick sites were as high as those reported from areas influenced by oil spills and municipal sewage outfall (148 ng/g in Rainio et al. 1986, 63–1,060 ng/g in Kveseth et al. 1982). However, only samples from the Boston Harbor station (MAIH) had concentrations as high as in industrialized areas affected by coking operations, as documented in Sydney Harbor, NS (1,400–16,000 ng/g) (Kieley et al. 1988) or smelting operations in Saudafijord, Norway (5,111–225,163 ng/g) (Bjorseth et al. 1979).

The wide range in ΣPAH_{24} concentrations suggests that sites with elevated concentrations may be in close proximity to recent or ongoing sources. Table 4 includes values for overall geometric means (GM) and GM +85% CL from the 1990 NS&T Mussel

TABLE 4.

Tissue organic concentrations (ng/g dry weight, mean ± SD) for Gulfwatch mussels in 1998.

Station	PAH	PCB	Chlorinated Pesticides
MASN	13.0 ± 2.0	27.2 ± 7.1	29 ± 3.0
MAIH	3330 ± 223	740 ± 39	133 ± 14.5
MAPR	553 ± 33	131 ± 7.8	60 ± 11.8
NHDP	231 ± 29	32 ± 8.5	16.1 ± 2.6
NHGP	164 ± 12.6	25.5 ± 1.5	14.1 ± 1.8
NHLH	78 ± 11.6	12.4 ± 1.8	102 ± 0.83
NHNM	645 ± 55	65 ± 9.1	67 ± 9.7
NHSS	187 ± 47	30 ± 5.4	14.6 ± 1.9
MECC	199 ± 25	42 ± 7.4	15.4 ± 2.3
MEKN	58 ± 19.6	16.7 ± 3.8	5.2 ± 0.49
MEDM	ND	3.7 ± 0.34	4.6 ± 0.50
MEBB	1120 ± 58	44 ± 5.5	61 ± 2.2
NBNR	106 ± 11.3	1.6 ± 0.18	7.0 ± 0.97
NBCH	24 ± 13.1	ND	6.5 ± 2.1
NBLN	13.8 ± 3.0	6.6 ± 0.50	5.3 ± 1.6
NBLB	16.2 ± 4.8	6.7 ± 1.3	5.8 ± 2.5
NBTC	164 ± 12.4	33 ± 5.2	13.8 ± 1.0
NBCG	229 ± 7.7	38 ± 2.3	37 ± 1.6
NSBC	133 ± 17.8	ND	5.1 ± 1.6
NSCW	138 ± 160	ND	2.5 ± 0.42
NSDI	106 ± 13.9	3.5 ± 0.43	6.0 ± 1.2
Geometric mean	127	23.5	13.6
LCL to UCL	40 to 401	8.8 to 62.6	5.9 to 31.6
NS&T Mussel Watch 1990 data (O'Connor & Beliaeff 1995)			
Geometric mean	270	110	36*
GM + 85% CI	1020	470	120*

The geometric mean and 85% confidence levels (CL) for all mussels are given below. $n = 4$ replicates per site.
ND = Not Detected.
* Value for DDT only.

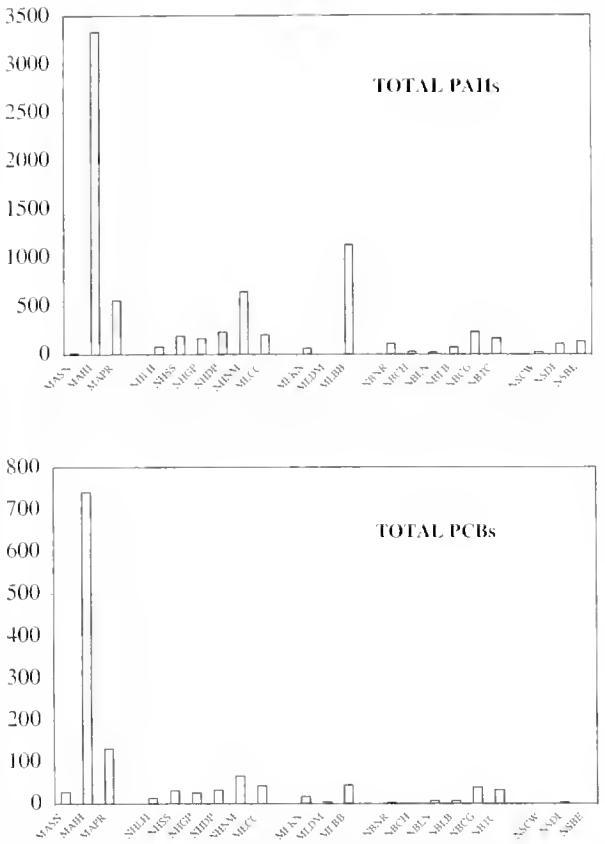

Figure 4. Distribution of total PAH and PCB tissue concentrations (arithmetic mean, µg/g dry weight) in mussels at all Gulfwatch stations in 1998.

Watch data (O'Connor & Beliaeff 1995) for comparison. Two sites, MEBB and MAIH, exceeded the NS&T GM +85% CL for PAH (1,020 ng/g DW), and two other sites, MAPR and NHNM, were at concentrations over half of this value. MAIH, and to a lesser degree MAPR, has been subject to high levels of all types of contamination. Relatively uncontaminated mussels deployed in 1995 had ~1,570 ng PAH/g DW after 60 days in cages at MAIH (Chase et al. 1996). MEBB (Boothbay Harbor, ME) had not been sampled since 1991 when organic analyses were not conducted. However, analysis of tissue samples showed mussels from MEBB to contain elevated levels of trace metals, especially Pb and Zn (Jones et al. 1998). Thus, it is a site that is apparently subject to a variety of contaminants, possibly because it is downstream from the Kennebec-Androscoggin watershed. The possible source of the PAHs at NHNM is not known. In contrast, mussels at NHDP, which was impacted by the 1996 *Provence* oil spill at the Schiller Station oil terminal, and at NHSS, which is in close proximity to the oil terminal, had much lower ΣPAH_{24} concentrations than at NHNM in 1998. Examination of the individual PAHs detected at NHNM reveals a marked dominance of higher molecular weight and nonalkylated PAHs (Chase et al. 2001). This pattern was consistent for all 1998 New Hampshire sites and suggests that the PAHs may be from pyrogenic sources, as opposed to recent petroleum sources. The pattern also strongly suggests that the sources may be historical, or reflect past exposure. Lower molecular weight PAHs degrade faster (Shiaris 1989) and are more mobile in the environment, and bivalves tend to metabolize and excrete higher molecular weight PAHs at slower rates (Widdows & Donkin 1992). Sediments from sites in North Mill Pond, especially upstream sites, had ΣPAH_{17} concentrations ranging from <690 to 23,600 ng/g DW (ANMP 1998). It is possible that PAH-contaminated sediments from upstream sources could be taken up and accumulated by mussels at the downstream NHNM site, especially during high flow or storm events at low tide.

The concentrations of ΣPCB_{24} ranged as widely as the ΣPAH_{24} concentrations. The mean of ΣPCB_{24} ranged from ND at NBCH, NSBC, and NSCW to 740 ng/g DW at MAIH (Table 4). Table 4 also shows the overall GM +85% CL of ΣPCB_{24} concentrations for all 1998 Gulfwatch sites. The same pattern of elevated concentrations in the southwest compared to the northeast sites can be seen. Two Massachusetts sites had the highest concentrations, MAIH (741 ng/g DW) and MAPR (131 ng/g DW). As described previously, MAIH is a site in Boston's Inner Harbor and has been subject to high levels of all types of contamination. Relatively uncontaminated (~37 ng ΣPCB_{24}/g DW) mussels deployed in 1995 had ~361 ng PCB/g DW after 60 days in cages at MAIH (Chase et al. 1996). In 1995, ΣPCB_{24} concentrations for MAPR, a site north of Boston Harbor, were the highest (131 ng/g DW) of any Gulf of Maine mussels sampled (Chase et al. 1996). Most of the New Hampshire sites exhibited relatively uniform and somewhat elevated concentrations relative to the Gulfwide geometric mean. The ΣPCB_{24} concentration at NHNM was the third highest of the 1998 sites at 65 ng/g DW. As with PAHs, the source of the PCBs in North Mill Pond is not known. Analysis of sediments from North Mill Pond conducted on samples collected in 1997 showed no detectable PCBs (ANMP 1998), although detection limits (>2,400 ng/g DW for seven Aroclors) were relatively high for that study. Sites in Portsmouth Harbor have had relatively high sediment PCB concentrations compared to other areas in the Gulf of Maine, except for Boston Harbor (ten Brink et al. 1997). The ΣPCB_{24} concentration in mussels at MEBB (44 ng/g DW) was also elevated compared to other 1998 sites, as was the case for other contaminants already mentioned.

It is instructive to look at data from New Hampshire as an example of how a regional database can be useful for interpreting local study results. Organic contaminant concentrations at NHNM are higher than at any other New Hampshire site (Table 4, Fig. 5), and this is a previously undocumented concern. Local community groups have focused on restoring this site, and it has been suspected to be a relatively contaminated site (ANMP 1998). However, in the context of the overall 1998 Gulfwatch database, NHNM has much lower ΣPAH_{24} and ΣPCB_{24} concentrations than at MAIH and either MAPR (ΣPCB_{24}) or MEBB (ΣPAH_{24}). Another characteristic of the New Hampshire data is that concentrations of both ΣPAH_{24} and ΣPCB_{24} are uniformly elevated compared to Gulfwatch sites north and east of New Hampshire, suggesting that there may be common sources for these relatively localized sites. Thus, interpretation of the New Hampshire data benefits greatly from comparison with the overall Gulfwatch database. Coordination of sampling and use of common laboratories for tissue analyses is a critical aspect of both programs that allows for added merit within the comparisons.

Another use of the Gulfwatch program in New Hampshire has been to document the effects of an oil spill on tissue PAH concentrations. On July 1, 1996, there was an oil spill from the vessel *Provence* into the Piscataqua River. Approximately 1,000 gallons of #6 fuel oil was dispersed with water currents into nearby areas

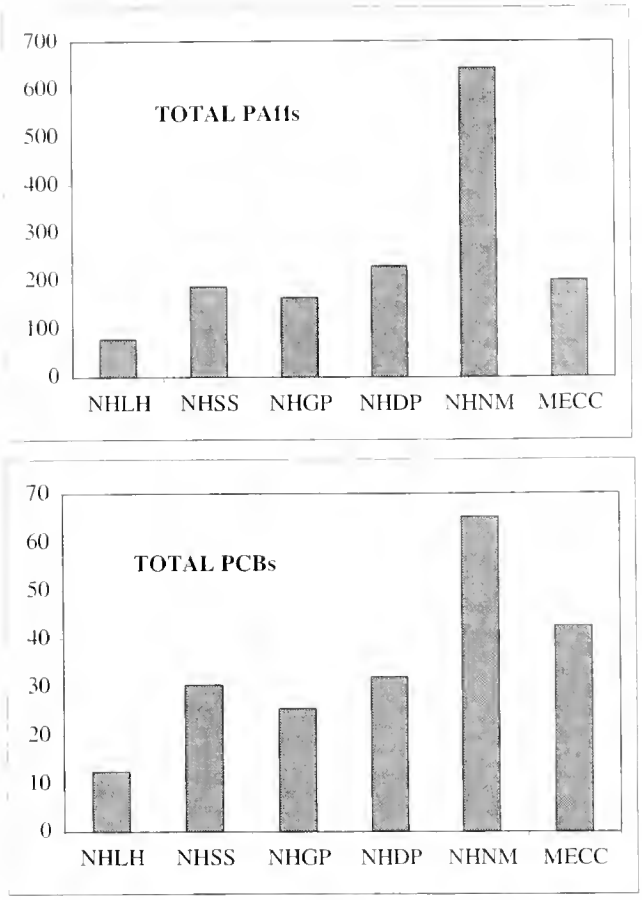

Figure 5. Distribution of total PAH and PCB tissue concentrations (arithmetic mean, µg/g dry weight) in mussels at New Hampshire Gulfwatch stations in 1998.

of the Great Bay Estuary. Fuel oils are known to contain a variety of PAHs, especially 2- to 4-ring PAHs, although hundreds of organic compounds, including larger PAHs, are present in all crude oils (Kennish 1997). The Gulfwatch station at Dover Point (NHDP), located at the confluence of the Piscataqua River and Little Bay approximately 2.5 miles upstream of the source of the oil spill, was sampled in 1994. Sampling was again conducted in July and October 1996 to determine if contaminants from the spill were taken up by mussels and to find the degree of elimination of the contaminants over time. The 1994 data serve as useful background information for assessing the degree of residual exposure of the 1996, 1997, and 1998 mussel tissue samples to the oil spill contaminants. ΣPAH_{24} concentrations were determined in mussel tissue samples collected in 1994, in 1996 on July 16 and October 1, 16 days and 3 mo, respectively, after the spill, and in 1997 and 1998 (Fig. 6). ΣPAH_{24} concentrations in the 1996/16-day samples were much higher than in 1994, as well as in comparison to other sites in New Hampshire. Elevated levels of PAHs were also observed in oysters (*Crassostrea virginica*) collected at another site impacted by the spill (Chase et al. 1997). The average ΣPAH_{24} concentrations were 639, 298, 266, 238, and 187 ng/g DW for the 16-day, 3 mo, 1997, 1998, and 1994 samples, respectively. Thus, the total PAH concentration has decreased greatly from 1996, less drastically from 1997 to 1998, and levels have almost returned to prespill (1994) levels.

Temporal Variation in Contaminant Concentrations

Sampling has occurred in up to five previous years at the five "benchmark" Gulfwatch stations to provide data for temporal trend analysis (Jones et al. 1998). Data for MECC, a benchmark station sampled since 1993, are presented here as one illustration of temporal trends in the Gulf of Maine (Table 5). There were few obvious trends in concentrations of trace metals and organic contaminants. Trends at the other four benchmark sites also showed variable results, with most discernable trends being decreases in contaminant concentrations. There has been significant variation for between-year comparisons for some contaminants (Chase et al. 2001).

Acceptable Levels and Standards of Mussel Contamination

Despite the wealth of information on the effects of toxic contaminants on a variety of species, limited information is available on observed human health effects resulting from the consumption of chemically contaminated shellfish. While documented epidemiological effects may be limited, the results of laboratory assays and isolated occurrences of acute human poisonings are responsible for focusing attention on human health impacts from eating chemically contaminated marine fish and shellfish. For example, in New Hampshire there are currently human consumption advisories for Hg and PCBs (NHDES 1998, NHEP 2001). The advisory for Hg is based on elevated Hg levels in inland lakes and rivers and is for all freshwater fish. For marine waters, there is a consumption advisory for both lobsters and bluefish based on elevated levels of PCBs. The PCB advisories for bluefish and lobsters are based on studies done in 1987 and 1991, respectively.

Published tolerance or action levels for PAHs in commercial marine species are not available in Canada or in the United States. Closure of commercial fisheries as a result of high contamination levels has been dealt with on a case-by-case basis in marine areas where PAH contamination may be a human health concern. In general, most concentrations reported in the literature are on a wet weight basis in contrast to Gulfwatch dry weight values. To facilitate general comparisons with Gulfwatch values, an average moisture content of 85% has been applied to wet weight health values to derive dry weight equivalents. All Gulfwatch organic concentrations are within acceptable concentrations for those compounds that have established FDA Action Limits in fish and shellfish. PCB concentrations found in Gulfwatch mussels (Table 4), including concentrations measured in MAIH mussels (0.74 ± 0.003 µg/g DW) are less than the action level of 13 µg/g dry weight (USFDA 1990, CSSP 1992). The action level for the pesticides dieldrin, aldrin, chlordane, heptachlor, and heptachlor epoxide is 2.0 µg/g dry weight (USFDA 1990). Only dieldrin and chlordane were detected in the 1998 mussel survey, but at concentrations barely above detection limits, which are orders of magnitude below the action levels. The total DDT concentrations found are several orders of magnitude below the action level of 33 µg/g dry weight (USFDA 1990, CSSP 1992). Canadian limits for agricultural chemicals exclusive of DDT are 0.67 µg/g DW.

As presented in Table 6, admissible levels of methyl mercury, expressed as µg Hg, are less than 6.7 µg/g dry weight, or 1 µg/g wet weight in the United States (USFDA 1990), and less than 3.3 µg/g dry weight, or 0.5 µg/g wet weight in Canada (CSSP 1992). The highest concentration of mercury found in the 1998 Gulfwatch study was 1.20 µg/g DW, in one replicate sample from the Schiller

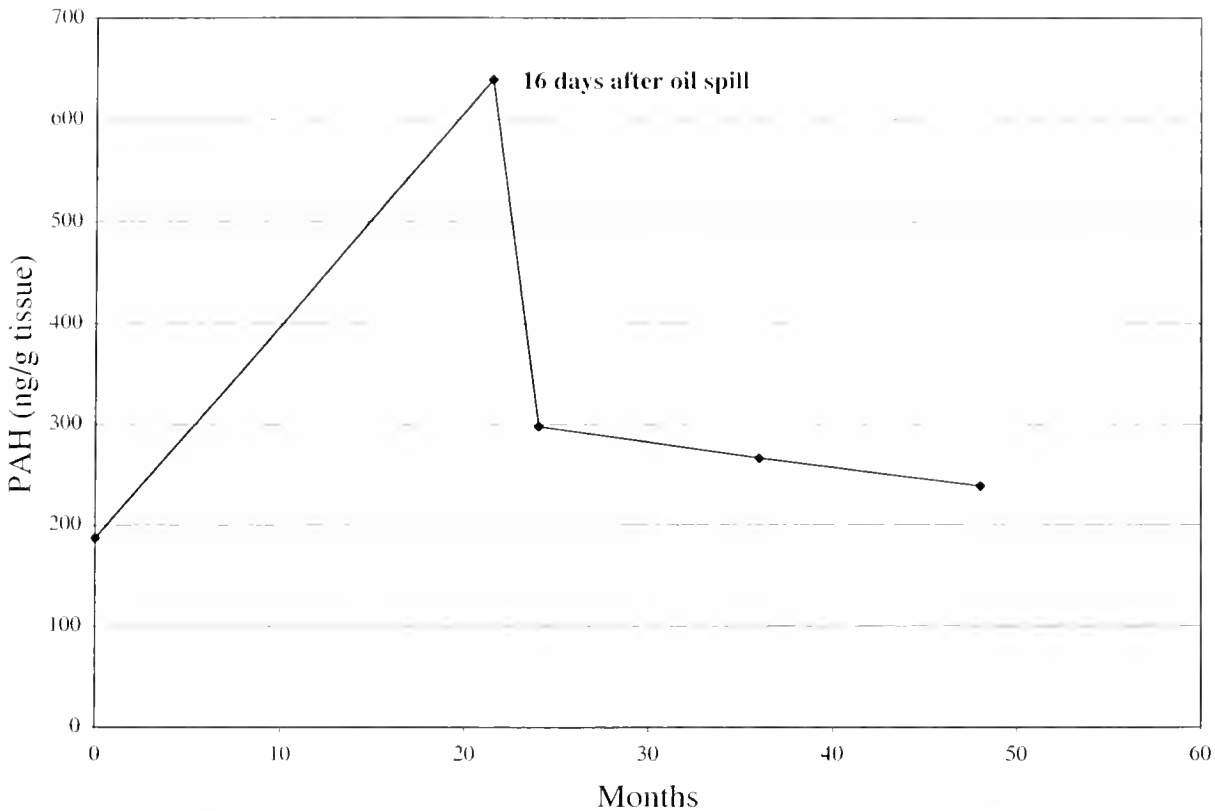

Figure 6. Long-term effects of a July 1996 oil spill on PAH contamination in mussels at Dover Point, NH. First PAH concentration sample collected in October 1994.

Station, New Hampshire, which is well below both federal action concentrations.

A series of FDA "Guidance Documents" (USFDA 1993) for cadmium, chromium, lead, and nickel was released in the United States to complement the FDA Mercury Action Level. These "alert" levels are guidelines and by themselves do not warrant the issuance of health advisories. In Table 6, guidance concentrations are reported on both wet weight and dry weight bases and are compared to the highest observed concentration in any single replicate analyzed in the 1998 Gulfwatch Project. All nickel, chromium, and cadmium concentrations in 1998 Gulfwatch mussels were well below the guideline values. However, Pb concentrations were above the FDA guideline alert level of 11.5 μg/g DW at MAIH and MEBB, and are thus of regional and local concern. The highest observed concentrations from the 1998 Gulfwatch data for other trace metals for which there is no guideline or action limit are included in Table 6. This highlights hot spots of localized elevated contamination as well as sites where elevated levels may also be

TABLE 5.

Long-term tissue contaminant concentrations (arithmetic mean ± SD) for a Gulfwatch baseline station: Clark Cove, ME (MECC).

Contaminant	1993	1994	1995	1996	1997	1998

			2.1 μg/g	Cornwallis, NS
Federal action concentration				
Hg (US)	1.0 μg/g	6.7 μg/g	1.2 μg/g	Schiller Station, NH
Hg (CA)	0.5 μg/g	3.3 μg/g		
No federal guideline or action concentration				
Highest observed 1998 Gulfwatch value				
Ag*		2.0/1.3		Coast Guard wharf, NB/Sandwich, MA
Al*		5640/440		Tin Can Beach, NB/Cornwallis, NS
Cu*		43/26		Coast Guard wharf, NB/Boston, Inner Harbor, MA
Fe*		2950/610		Tin Can Beach, NB/Boston Inner Harbor, MA
Zn		310		Boston Inner Harbor, MA

* Two values for some metals are presented because the highest values are all from New Brunswick sites where tissue samples tended to contain excessive inorganic sediment, as indicated by elevated Al and Fe concentrations.

† Gulfwatch highest values exceed U.S. FDA Guideline concentration. Four replicate sample concentrations ranged from 30–37 μg/g DW at MAIH and 13–18 μg/g DW at MEBB.

associated with excessive sediment in tissue samples (New Brunswick sites). Many of the areas with elevated concentrations are currently under more detailed investigations by other agencies.

ACKNOWLEDGMENTS

The authors are grateful to the following individuals: Noel Carlson, Andrea Riley, Deb Lamson at UNH/JEL, Joanne McLaughlin at NHOSP, and Andrea Bowman, Amber Currier, Paul Currier, Rob Livingston, and Eric Williams at NHDES. All authors on previous Gulfwatch annual reports are gratefully acknowledged for their contributions to the conceptual framework and some of the program-consistent text for this report. Generous financial support for the program came from NOAA, the New Hampshire Department of Environmental Services, the Gulf of Maine Council on the Marine Environment, and Environment Canada. Community groups in Canada, ACAP St. John and ACAP Charlotte Waterways, are also acknowledged for their help with sampling and supporting the 1998 program.

DISTRIBUTION PATTERNS OF POLYCHLORINATED BIPHENYL CONGENERS IN MARINE SEDIMENTS AND WILD MUSSELS FROM GALICIA COAST (NORTHWESTERN SPAIN)

N. CARRO,* Y. SAAVEDRA, I. GARCIA, M. IGNACIO, AND J. MANEIRO

Centro de Control de Calidad del Medio Marino, Peirao de Vilaxoán s/n, 36611, Vilagarcía de Arousa, Pontevedra, Spain

ABSTRACT To know distribution patterns of polychlorinated biphenyl congeners in the marine environment from Galicia, polychlorinated biphenyls (PCBs) no. 31, 28, 52, 101, 118, 153, 105, 138, 156, and 180 were isolated by Soxhlet extraction in wild mussels and surface marine sediments; the quantification was performed using gas chromatography-mass spectrometry (GC-MS) and gas chromatography-electron capture detection (GC-ECD). PCBs 101, 138, 153, and 180 were the most abundant congeners in all samples analyzed. Distribution of PCB congeners was shifted in favor of higher chlorinated compounds. By means of multivariate techniques of data exploration, such as hierarchical cluster analysis and principal components analysis, mussel samples from contaminated (Ferrol and A Coruña zones) areas were clearly separated from uncontaminated (all the other samples) areas. Sediment samples were more heterogeneous. If tri- and tetrachlorinated biphenyls were considered when carrying out the multivariate analysis, Vilaboa samples formed a group differentiated from the other samples.

KEY WORDS: polychlorinated biphenyls (PCBs), wild mussels, marine sediments, principal components analysis (PCA), hierarchical cluster analysis (HCA)

INTRODUCTION

The increase of human activity and industrial development in Galicia is intensely disturbing the natural marine environment. Its progressive deterioration is mainly caused by contributions of various different industrial discharges that reach the coast without previous treatment or purification. Taking into account the high importance of shellfishing in Galicia, especially bivalve mollusks (the aquaculture of mussels is one of the main resources), it is necessary to carry out a baseline analysis of micropollutants in the estuarine bays ("Rías") from Galicia.

Polychlorinated biphenyls (PCBs) are considered to be thermally, chemically, and physically stable micropollutants; this stability has been responsible for PCB marine environmental contamination problems (Erickson 1997). PCB compounds are volatile, lipophilic, and persistent. They tend to bioaccumulate and bioconcentrate in fatty tissues of biota and to associate with benthic and suspended sediments (Berger & Brevik 1996, Beyer et al. 1996). Mussels, with low PCB metabolism, are a good coastal indicator for micropollutants in the water column and sediments.

Various instrumental techniques are available for the extraction and determination of PCBs in environmental samples. Techniques for the extraction of PCBs include Soxhlet extraction (Piñeiro et al. 1996), microwave-assisted extraction (MAE) (Carro et al. 2000, Carro et al. 1999b), Supercritical fluid extraction (SFE) (Hawthorne et al. 1993, Soren & Berit 1994), solid phase microextraction (SPME) (Llompart et al. 1999), solid phase extraction (SPE), accelerated solvent extraction (ASE) (Bandh et al. 1998) and others; techniques for the determination include gas chromatography-electron capture detection (GC-ECD) (Chen & Ling 1992), gas chromatography-mass spectrometry (GC-MS) (Pavoni et al. 1991, Leonards et al. 1996, Shin & Oh-Shin 1999), gas chromatography-atomic emission detection (GC-AED), gas chromatography-Fourier transform infrared (GC-FTIR) (Hembree et al. 1993), and others. Previous works on distribution of chlorinated biphenyls in mollusks from some Galicia estuarine bays were developed using different extraction methods (Fumega et al. 1984, Franco et al. 1984, Fernández Muiño et al. 1991, Alvárez Piñeiro et al. 1994, Alvárez Piñeiro et al. 1995).

The objective of this study was to describe the distribution of PCBs in wild mussels (*Mytilus galloprovincialis*) and in surface marine sediments collected from 19 sites in the Galicia coast. Ten PCB compounds (IUPAC No. 31, 28, 52, 101, 118, 153, 105, 138, 156, and 180) recommended by the International Council for Exploration of the Seas (ICES) (Duinker et al. 1988) have been isolated using Soxhlet extraction and analyzed by GC-ECD and GC-MS. Multivariate techniques of data exploration as hierarchical cluster analysis (HCA) and principal component analysis (PCA) have been applied to sediments and mussels data.

MATERIALS AND METHODS

Materials and Apparatus

Dichloromethane, n-pentane, and isooctane for organic trace analysis were purchased from Merck (Darmstadt, Germany); aluminum oxide, silica gel, and anhydrous sodium sulfate were also purchased from Merck. Copper turnings were supplied by Aldrich (Steinheim, Germany). Analytical reagent grade PCB individual congener standards were purchased from Dr. Ehrenstorfer (Augsburg, Germany).

Wild mussels (*Mytilus galloprovincialis*) and surface sediments were collected from 19 coastal subzones in the Estuarine Bays ("Rías") from Galicia (December 1999): Ribadeo (Ría de Ribadeo), Foz (Ría de Foz), and O Vicedo (Ría do Barqueiro) from Lugo zone (samples labeled as 1); As Pías Montón, As Pías Puntal, Barallobre, and Mugardos (Ría de Ferrol), Pontedeume (Ría de Ares), and Miño (Ría de Betanzos) from Ferrol zone (samples labeled as 2); Santa Cruz and Pasaxe (Ría de A Coruña) from A Coruña zone (sample labeled as 3); Anllóns (Ría de Corme-Laxe), Camariñas (Ría de Camariñas), and Corcubión (Ría de Corcubión) from Costa da Morte zone (samples labeled as 4); Raxó and Lourizán (Ría de Pontevedra), Vilaboa, Arcade, and Baiona (Ría de Vigo) from Pontevedra zone (samples labeled as 5) (see Fig. 1).

Two certified reference materials, HS-2 (Canadian marine sediment) supplied by National Research Council of Canada and IAEA 142 (mussel tissue homogenate) supplied by International Atomic

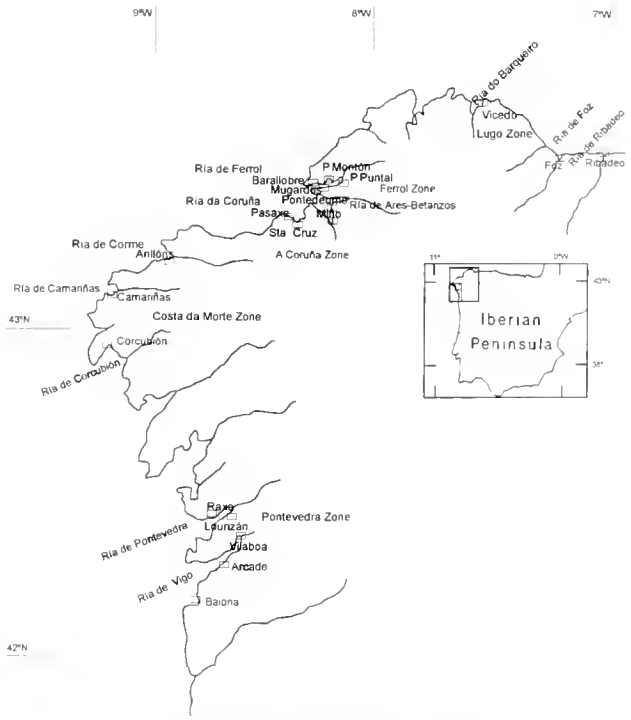

Figure 1. Map with sampling points.

Energy Agency (Vienna, Austria), were used for quality control. Standard stock solutions were prepared by weighing an appropriate amount of each standard and diluting to 5 mL with isooctane. Working solutions were made by appropriate dilution of the stock solution. All solutions were stored at 4 C. For quantitative gas chromatographic determinations, calibration was carried out at four concentration levels for each congener spanning the range of 4–100 μL and using CB 155 (1 mg/L) as an internal standard.

The concentrated extracts were analyzed by gas chromatography using a Perkin-Elmer Autosystem gas chromatograph equipped with an electron capture detector. A TRB-5 (Teknokroma, Spain) 5% diphenyldimethyl siloxane capillary column (60 m × 0.20 mm i.d. × 0.4 μm phase thickness) was used. The chromatographic conditions were as follows: the column temperature program was 90°C (3 min) to 215°C (40 min) at 30°C/min and 275°C (30 min) at 5°C/min; the injector temperature (splitless mode, 1.8 min) was 270°C; the electron capture detector temperature was 365°C; carrier gas was hydrogen supplied by Air Liquid (Spain). The identification of extracted compounds was performed on a Varian Saturn 2000 gas chromatograph-ion trap detector mass spectrometer. The chromatographic conditions and capillary column were identical to those described above; carrier gas was helium supplied by Air Liquid (Spain). The mass conditions were: the trap temperature 170°C; the scan range 100–400 m/z; the multiplier delay 5 min; the emission current 10 μA; the multiplier voltage 1,450 V; the maximum ionization time 25,000 μsec; and the manifold temperature 120°C.

Data numerical analysis was carried out by means of the statistical package (SPSS Inc.; 1989–1999 V.9.0).

Sample Preparation

Thirty individual mussels of similar sizes (40–80 mm) were used for each analysis. Homogenates of the mussel flesh were frozen (-30°C), freeze-dried and Soxhlet extracted (5 g of sample; 150 mL of dichloromethane-pentane, 1–1; 8 h) by duplicate, and the extract was concentrated under vacuum evaporation to approximately 1 mL. An aliquot of the extract was used to determine gravimetrically the lipid content. Lipids were removed from an appropriate portion of the concentrate by chromatography over alumina (6% deactivated) and the CB fraction was purified by chromatography on silica (1% deactivated). CB 155 was added as an internal standard prior to analysis by gas chromatography.

Sediments were collected by hand using a metal scoop at 0–30 cm depth and immediately frozen (−30°C). The sediments were freeze-dried and sieved to obtain a particle size below 63 μm. Activated copper turnings were used to remove elemental sulfur during Soxhlet extraction (5 g of sample; 150 mL of dichloromethane-pentane, 1–1; 8 h) in duplicate. The sediment extracts were concentrated under vacuum evaporation to 1 mL and were treated in the same manner as the mussel samples.

RESULTS AND DISCUSSION

Validation of Analytical Procedure of PCB Compounds

Calibration curves were obtained at four concentration levels using adequately diluted standards. Each concentration level was injected in duplicate, and peak heights were fitted by linear regression. The correlation coefficient was 0.999 for all the target compounds.

Method reproducibility experiments were carried out in five replicate mussel and sediment samples, providing a mean relative standard deviation of 8.8% and 12.71%, respectively; the mean recoveries of PCBs were 92.09% and 101.31% from mussel and sediment samples, respectively.

Individual Congener Concentrations: Univariate Analysis

Concentrations of individual congeners of PCBs (IUPAC No. 31, 28, 52, 101, 118, 153, 105, 138, 156, and 180) expressed as the average of two analytical replicates in ng/g dry weight (dw) from mussels and marine sediments and lipid content of mussels in percentage of studied subzones are summarized in Tables 1 and 2.

The contents of PCBs in wild mussels and marine sediments varied from 0.06 ng/g to 115 ng/g dw and from 0.01 to 19.4 ng/g dw, respectively. In both mussels and marine sediments, congeners making the largest individual contributions to total congener concentration (sum of 10 congeners) were the penta-, hexa-, and heptachlorobiphenyls (PCBs 101, 138, 153, and 180); these compounds are less volatile, more resistant to metabolic and microbial degradation, adsorb readily to sediments, and are more soluble in lipids than lower chlorinated congeners (Shiu & Mackay 1986). The low concentrations of tri- and tetrachlorobiphenyls (PCBs 28, 31, and 52) in samples were due to their higher volatility, low partition coefficient between n-octanol and water (greater aqueous solubility), and higher tendency to biodegradation in marine sediments (Bright et al. 1995). However, the Vilaboa subzone showed very high levels of lower chlorinated compounds, mainly in the sediment sample; these results will be discussed below.

In general, concentrations of PCBs in mussels coming from the same zone were very homogenous; levels of PCBs in mussels collected from Ferrol and A Coruña zones (labeled as 2 and 3, respectively), which possessed the greatest lipid contents, were higher than those found in the other zones; it is logical because these areas present the largest degree of urbanization and indus-

TABLE 1.

Mean of concentration of PCBs (ng/gdw) and lipid content (%) in mussels from Galicia coast.

trialization in Galicia. PCB concentrations in sediment samples showed a greater intrazonal heterogeneity.

To select the most significant variable to distinguish between the studied zones, data in Tables 1 and 2 were subjected to univariate analysis. A one-way analysis of variance (ANOVA) revealed that CB153 (present in enhanced concentrations in industrial mixtures) was the most significant variable for mussel and sediment samples; Figure 2 shows the box-whisker plot corresponding to this variable.

Congener Distribution Patterns: Multivariate Analysis

In view of the previous results, it was logical to use the set of variables at hand to achieve more precise distinction of the zones. Hence, the data (in the case of mussels, normalized to lipid content) in Tables 1 and 2 were subjected to PCA and HCA. Initially, both types of multivariate analysis were applied separately to data for the mussel and sediment samples.

Mussel Samples

Cluster analysis of data (concentration of higher chlorinated biphenyls, CBs 101, 118, 153, 105, 138, 156, and 180) for the mussel samples using the average linkage method led to two fairly robust clusters (Fig. 3A). The most compact cluster was formed by the samples from Ría de Ferrol (zone labeled as 2) and Ría de A Coruña (zone labeled as 3), the most contaminated zones; at higher

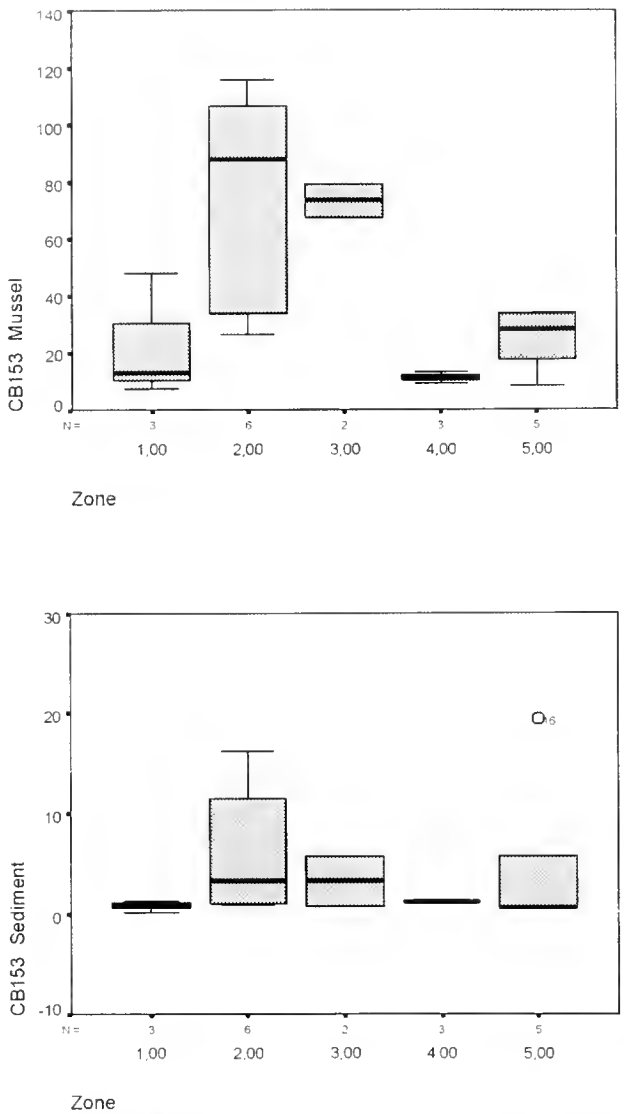

Figure 2. Box-whisker plot of CB153 for the five sampling zones (mussel and sediment samples). Data are divided into areas of equal frequency. Box: middle 50% frequency. Lower whisker: from the first quartile to the smallest data point. Upper whisker: from the third quartile to the largest data point.

similarity, these samples were separated in two new clusters that grouped mussels from Ría de Ferrol and Ría de A Coruña, respectively. The other principal cluster (less compact) was formed by samples from slightly contaminated zones. Mussel samples from Pontedeume and Miño subzones (Ría de Ares and Ría de Betanzos, respectively) belonging to Ferrol zone (labeled as 2) were placed in this cluster. If tri- and tetrachlorobiphenyls (CBs 31, 28, and 52) were used to carry out the cluster analysis, mussels from Vilaboa subzone (Pontevedra zone, labeled as 5) were clearly differentiated from all the others (Fig. 3B).

The same conclusions are extracted using PCA: retaining the first two factors, 85.93% of the initial variance was explained (PC1, 66.42%; PC2, 19.51%). Figure 4 shows the projection of the objects (sampling subzones) on the plane of the first two components. Ría de Ferrol and Ría de A Coruña samples were associated with the positive part of the first component that comprised the penta-, hexa-, and heptachlorobiphenyls. The distribution of the uncontaminated samples group was mainly influenced by the negative part of the first factor. The Vilaboa sample was associated with the second component that was constructed with the CBs 31, 28, and 52 contribution.

In mussel samples, CB 153 and the other higher polychlorinated biphenyls showed a clear differentiation between contaminated and uncontaminated zones independently of the geographical proximity. Pollution of industrial zones does not reach the nonindustrialized sites; this behavior can be mainly observed in Ferrol zone. Pontedeume and Miño subzones are slightly contaminated and are considered as unspoiled and not industrialized areas, while the other subzones (P. Puntal, P. Montón, Mugardos, and Barallobre) are highly contaminated industrial and urbanized areas. Actually, there are no studies of water flows in the Ferrol zone but the distribution of PCB compounds suggest that the water circulation of the estuarine bays (Ares, Betanzos, and Ferrol) is very slow in this area.

Lourizán and Vilaboa subzones presented high contents of PCBs. Lourizán is placed near to Pontevedra city with an important pulp paper and chlorine bleaching mill; Vilaboa is sited near to the most industrialized city in Galicia (Vigo) and placed in a very closed zone of the estuarine bay.

Sediment Samples

Cluster analysis of data (sum of congeners) for the sediment samples using the average linkage method (Fig. 5) distinguished two groups. One of the groups included the most contaminated sediments, Barallobre subzone (sample labeled as 2) and Lourizán subzone (sample labeled as 5). The other group consisted of two subgroups. The first subgroup included the slightly contaminated samples Mugardos and Montón subzones (samples labeled as 2) and Pasaxe subzone (sample labeled as 3) and Vilaboa subzone (sample labeled as 5). The second subgroup included the least contaminated samples. Analytical results for all of the sediment samples were more heterogeneous than for the mussel samples.

Sediment samples from Lourizán and Vilaboa subzones with a high content of total organic carbon (TOC) (silty muds) presented a greater concentration of PCBs in comparison with expected values of concentration from their mussel samples. This could be due to the particular conditions developed in these subzones that produce a low PCBs bioavailability from sediments to mollusks; these subzones are sited in very stagnant areas in the estuarine bay where redissolution of organic compounds from sea bottom to water is improbable. Moreover, the high content of total organic carbon in sediments causes a high accumulation of PCBs (hydrophobic contaminants) because they tend to be strongly associated with organic-rich particles. These sediments can act as a temporary pollutant trap before accumulation in biota. In general, the bioavailability and toxicity of sediment-associated contaminants decrease with increasing TOC content (Lake et al. 1990). In further research, the TOC values of sediments (with different structures and compositions) will be considered to attain a good geographical comparison and a correct data interpretation in contamination studies. The sediment TOC and the lipid content of the organisms are key factors in the partitioning of organic contaminants.

Mussels from Puntal (sample labeled as 2) and Sta Cristina (sample labeled as 3) subzones had a higher concentration of PCBs than their corresponding sediment samples. This could be due to the low depth of sampled sediments (0–30 cm). In these subzones, the surface sediment, placed in a tidewater zone, is a "clean" sandy

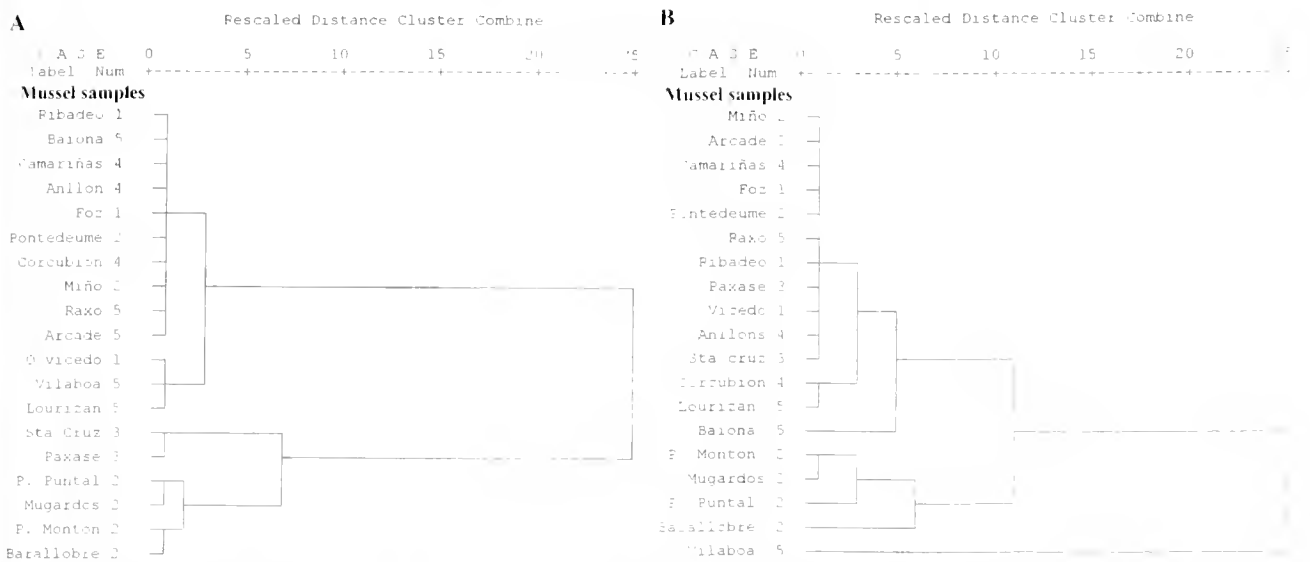

Figure 3. (A) Dendrogram showing the results of a hierarchical cluster analysis on higher chlorinated biphenyl distributions in Galicia mussels. (B) Dendrogram showing the results of a hierarchical cluster analysis on lower chlorinated biphenyl distributions in Galicia mussels.

deposit with very low levels of TOC and organic pollutants. Sometimes, accumulation of contaminants in several species (including mussels) does not depend on pollutant concentration in sediments but it can be strongly affected by a selective uptake of contaminated food. In these zones, the local (urban) point discharges are frequent.

If only tri- and tetrachlorobiphenyls CBs 28, 31, and 52 were considered when carrying out the cluster analysis, the sample from Vilaboa was clearly differentiated from all the others; the behavior was similar to the mussel sample.

Two principal components were found to account for about 91.25% of the initial variance. The most contaminated group is associated with the first component (constructed with penta-, hexa-, and heptachlorinated biphenyls). The Vilaboa sample is related to the positive part of the first and second components (the latter is constructed with tri- and tetrachlorinated biphenyls).

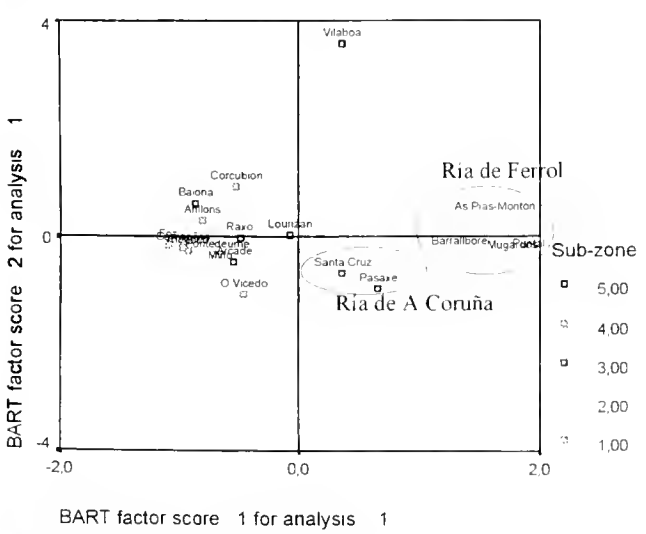

Figure 4. Distribution of mussels in the plane of the first and second component.

Correlation between Mussels and Sediments from the Same Zone

Due to the cycling of micropollutants in marine inlets, mussels and marine sediments must be significantly correlated in a unique manner that should predict the general distribution patterns of PCBs. In this way, the possible sources of organic micropollutants can be detected and actions initiated.

To confirm this hypothesis, the data sets in Tables 1 and 2 were subjected to multivariate analysis. In general, cluster analysis in Figure 6A shows separation between sediments and mussels, but there are some slightly contaminated mussels that were placed in the sediment cluster and some highly contaminated sediments (Lourizán subzone) that were placed in the mussel cluster (Baiona, Camariñas, Anllón subzones). Mussels of Ría de Ferrol were clearly separated from all samples.

If only tri- and tetrachlorinated biphenyls are considered, Vila-

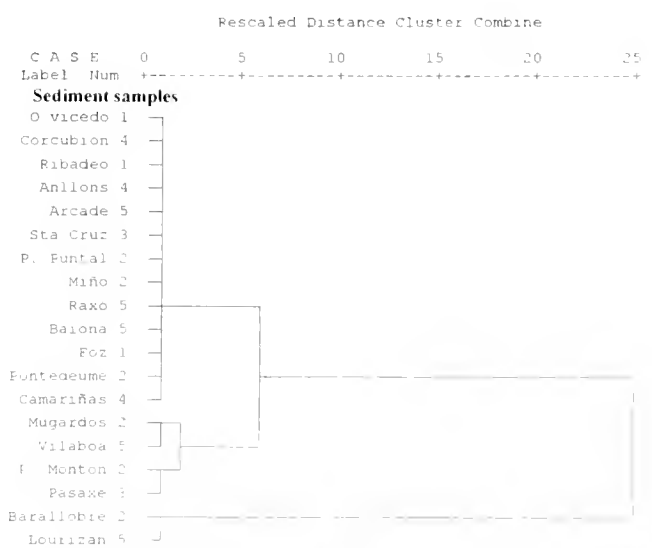

Figure 5. Dendrogram of Galicia sediments. Sum of congeners was considered to carry out cluster analysis.

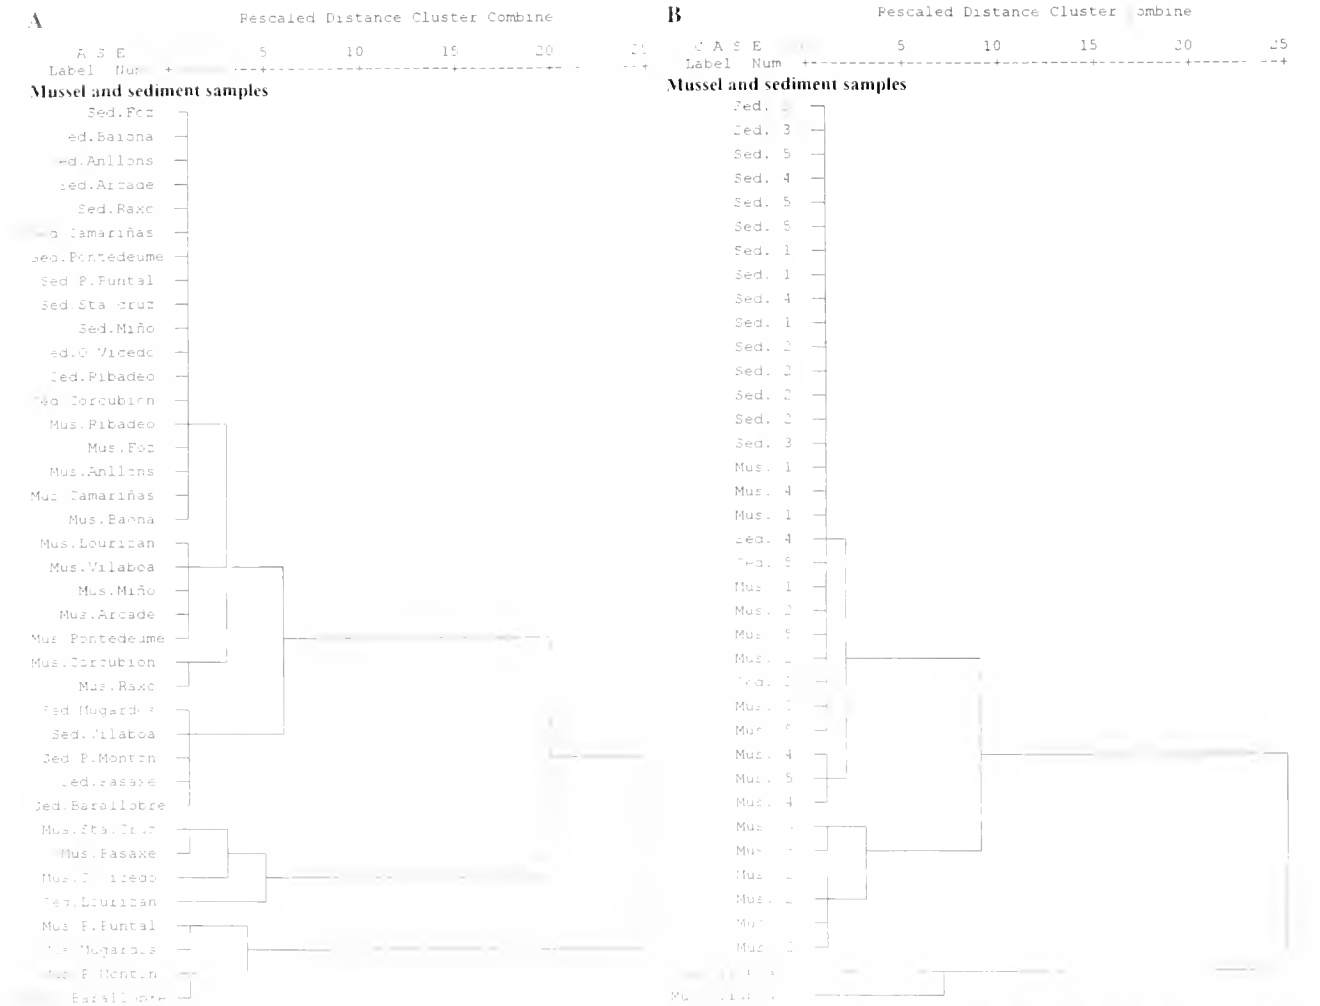

Figure 6. (A) Dendrogram showing the results of a hierarchical cluster analysis on chlorinated biphenyl distributions in Galicia mussels and sediments. (B) Dendrogram showing the results of a hierarchical cluster analysis on lower chlorinated biphenyl distributions in Galicia mussels and sediments.

boa samples (mussels and sediments) were closely grouped (Fig. 6B). The abnormal behavior of the Vilaboa subzone with regard to lower chlorinated biphenyls is probably related to several factors that can cause some special conditions in the aquatic system. The Vilaboa subzone can be considered as an undisturbed area because the presence of strong air and water flows is unlikely, so a major contribution of the highly volatile compounds (with a high vapor pressure) can be caused by atmospheric input. These compounds can be present in sufficient concentrations so that they remain in a free phase and are not dissolved in water.

Sediments from Vilaboa subzone possessed high organic carbon contents. This may influence the fate and bioavailability of some contaminants by affecting physicochemical characteristics, such as water solubility, sorption capacity, fugacity, and partitioning (Kenaga & Goring 1980). It is also known that under anaerobic conditions, microorganisms can partially dechlorinate the more highly chlorinated congeners producing the lower chlorinated compounds (Erickson 1997).

There are reasons to believe that PCB composition will change with time in environmental samples and that the resulting proportions of congeners will not resemble the pattern of industrial mixtures. The lack of definitive assignments of congener composition

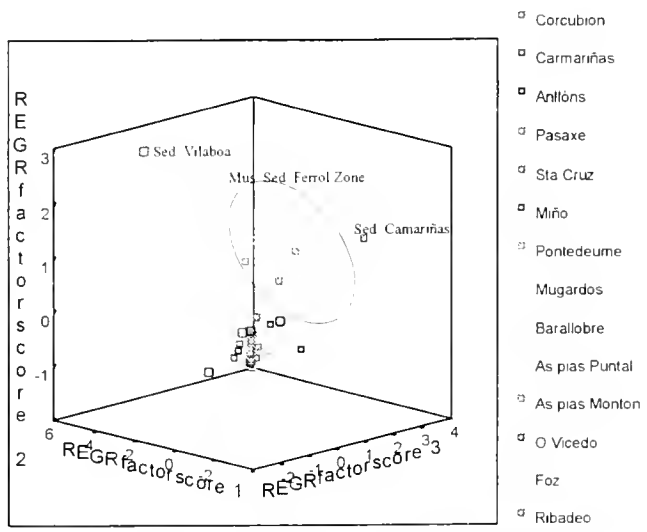

Figure 7. Distribution of Galicia mussels and sediments in the first three principal components (Varimax rotated).

of industrial mixtures and other products contributes to an ignorance of the possible transformations of these compounds in the animal tissues and, in general, in all environmental samples (water, sediment, soil, atmosphere, etc.).

PCA followed the cluster analysis. With the first two factors, 83.46% of initial variance is explained. A representation of the first three rotated (Varimax) components is shown in Figure 7. In the tridimensional space, three sample groups can be identified: the first is closely related to the positive part of the second axis (Vilaboa sediment). The distribution of the second group (mussels and sediments from Ferrol zone, mussels from P. Montón, P. Puntal, Barallobre, and Mugardos and sediments from P. Montón, Pontedeume, Barallobre, and Mugardos) is mainly influenced by the positive part of the first factor. Finally the third group (all the other samples) is related to the negative part of the second axis.

By means of cluster analysis and principal component analysis, the most polluted samples (i.e., the group of Ferrol zone samples of mussels and sediments) and the group of Vilaboa samples (mussels and sediments) were separated from the more heterogeneous group. This study has described the profile and base levels of the organochlorine pollution in estuarine bays from Galicia. In this way, we can now detect abnormal concentrations and possible sources of these compounds that may damage marine water quality and shellfish culture destined for human consumption.

ACKNOWLEDGMENT

We would like to thank A. Mouteira for sample preparation.

ABSTRACT The sanitary classification of harvesting areas for bivalve mollusks in France is based on the level of *Escherichia coli* contamination detected in shellfish meat, as defined in EC Directive 91/492 EEC. However, outbreaks of gastroenteritis or hepatitis after consumption of shellfish meeting current bacteriological standards suggest that *E. coli* is a poor indicator of viral contamination. The purpose of this study was to assess the adequacy of enterovirus and F-specific RNA bacteriophages as new indicators of human enteric viruses. Shellfish were sampled over a 37-mo period to characterize microbial contamination in two coastal areas subjected to different sewage contamination inputs. Contamination by *E. coli*, F-specific RNA bacteriophages (F+ RNA) and human enteric viruses (enterovirus, EV; hepatitis A virus, HAV; Norwalk-like virus, NLV; astrovirus, AV; and rotavirus, RV) was measured in the same samples. *E. coli* analysis was performed by conductance measurement, enteric viruses were detected by reverse-transcription polymerase chain reaction (RT-PCR) and hybridization, and F+ RNA was evaluated by culture according to the ISO 10705-1 method. Statistical analysis based on bootstrap methods was performed on 95 series of paired observations. The validity of *E. coli*, enterovirus, and F-specific RNA bacteriophages as viral indicators was evaluated by measuring their sensitivity and specificity in the presence of enteric viruses. None of the tested indicators proved adequate to protect the public from viral shellfish contamination. The sensitivity of all indicators was better in the highly contaminated zone, and enteroviruses showed the highest specificity for both sites.

KEY WORDS: indicator, *Escherichia coli*, F-specific RNA bacteriophages, enteric viruses, viral contamination, shellfish

INTRODUCTION

Determination of the microbiological sanitary quality of shellfish-growing waters is based on the use of fecal coliforms to evaluate the presence of fecal pollution. In Europe, sanitary criteria are currently established by EC Directive 91/492 EEC. However, previous studies have shown that there is very little relationship between traditional fecal indicators and the presence of viral pathogens (Le Guyader et al. 1994, Doré & Lees 1995, Tree et al. 1997, Lee et al. 1997, Le Guyader et al. 1998). This has been confirmed by outbreaks of viral gastroenteritis or hepatitis after consumption of shellfish meeting current bacteriological standards (Dowell et al. 1995, Lees et al. 1995).

In fact, fecal coliforms are rather poor indicators of viral contamination because they are different than viruses in their resistance to environmental conditions, sewage, or water treatment processes and marine water. They only survive in seawater for a few days, whereas viruses can persist for several months. A few other microbial organisms, such as enteroviruses and bacteriophages, have been proposed as alternative sanitary indicator organisms. As viruses, their survival conditions in seawater should be similar to those of enteric viruses (Havelaar 1993, Metcalf et al. 1995, Maillard 1996, Sobsey 1997). Three main groups of bacteriophages are of particular interest as potential indicators: somatic phages, *Bacteroides fragilis* phages, and F-specific RNA phages. Analysis of existing studies (Lee et al. 1997, Tree et al. 1997, Havelaar et al. 1993) indicated that the last two groups were most suitable for tracing fecal contamination. However, the limited number of *B. fragilis* phages in the environment, as well as methodological difficulties in detecting them, have led some researchers to choose F-specific RNA phages as potential indicators of viral risk in shellfish (Lee et al. 1997). The relation between these indicators and enteric viruses in environmental samples (wastewater, groundwater, fresh and marine waters, and shellfish) is uncertain. Some authors have found a good correlation between these candidate indicators and viruses (Gantzer et al. 1998, Havelaar et al. 1993), whereas others are more doubtful (Legnani et al. 1998, Ricca & Cooney 1999, Griffin et al. 1999, Leclerc et al. 2000).

The purpose of this study was to compare the validity of *E. coli*, enterovirus, and F-specific RNA bacteriophages as viral indicators by measuring the sensitivity and specificity of each candidate in the presence of enteric viruses.

MATERIALS AND METHODS

Environmental Sampling

Shellfish samples were collected over a 3-y period (September 1995 to September 1998) in two coastal areas with different pollution levels. Forty-seven oyster (*Crassostrea gigas*; Thunberg, 1793) samples were collected at three sampling points in a shellfish area temporarily classified as a category A site (site 1) and 48 mussel (*Mytilus galloprovincialis*; Lamarck, 1819) samples at two sampling points in a highly contaminated area not open to shellfish commercialization (site 2). Sample collection was uniform throughout the year: 45% during the autumn-winter season (respectively, 47% in site 1 and 44% in site 2) and 55% during the spring-summer season (respectively, 53% in site 1 and 56% in site 2). Contamination by *Escherichia coli*, F-specific RNA bacteriophages (F+ RNA), and human enteric viruses (enterovirus, EV; hepatitis A virus, HAV; Norwalk-like virus, NLV; astrovirus, AV; and rotavirus, RV) was evaluated in the same samples.

TABLE 1.

Sensitivity and specificity measurements of an indicator.

	Viral Contamination	
	Yes	No
Positive level of indicator	TP	FP
Negative level of indicator	FN	TN

Sensitivity = TP/(TP + FN). Specificity = TN/(TN + FP).
TP: true-positive; FN: false-negative; FP: false-positive; TN: true-negative.

Microbiological Analyses

E. coli

Quantitative estimation of fecal indicators (*E. coli*) in shellfish was performed by conductance measurements (Dupont et al. 1996). The detection threshold of the conductance method is 30 *E. coli* per 100 g of shellfish (meat and liquor).

Enteric Viruses and Bacteriophages

Upon reception in the laboratory, 10 to 12 shellfish were washed and shucked, and the stomach and digestive tissues were dissected, mixed, aliquoted, and frozen. For analysis, one aliquot was thawed on ice and crushed. Viruses, enteric viruses, and F+ RNA were concentrated by PEG precipitation, as previously described (Atmar et al. 1995).

For human enteric virus detection, the PEG pellet was suspended in phosphate buffer and nucleic acid and purified as previously described (Atmar et al. 1995). All primers, probes, and reverse-transcription polymerase chain reaction (RT-PCR) conditions have already been reported and used in different studies (Le Guyader et al. 2000).

For F-specific RNA bacteriophage enumeration, the PEG pellet was then suspended in 3 mL of peptone water, and F+ RNA phages were detected according to the ISO 10705 (1) 1995 method. The double agar overlay technique was used for preparation and determination of phage stocks and enumeration of the coliphage content of oysters. The F+ RNA assay was performed with host *Salmonella typhimurium* WG49. The detection thresholds of the assay were 2.5 PFU/1.5 g of digestive tissue for oysters and 5 PFU/1.5 g of digestive tissue for mussels.

Data Analysis

Data were first summarized by the minimum, maximum, and geometric mean of the shellfish concentration for *E. coli* and F+ RNA and by the presence or absence of detection for enteric viruses (EV, HAV, NLV, AV, and RV). The validity of an indicator organism to discriminate shellfish samples contaminated by virus was evaluated using the sensitivity of each candidate indicator organism for virus detection. The accuracy of identifying samples with no viral contamination was estimated by the specificity of the indicator.

Sensitivity was defined as the ratio of the number of true-positive values (positive level of the candidate indicator organism in the presence of virus) to the number of true-positive values plus the number of false-negative values (negative level of the candidate indicator organism in the presence of virus). Specificity was defined as the ratio of the number of true-negative values (negative level of the candidate indicator organism in the absence of virus) to the number of true-negative values plus the number of false-positive values (positive level of the candidate indicator organism in the absence of virus) (Table 1). Sensitivity and specificity estimates ranged between 0 and 1 (or 0% and 100%). Ideally, the best indicator should have a sensitivity and specificity of 1 (or 100%).

An indicator was considered to be positive or negative according to a specific threshold. The negative level of the threshold was less than 230 *E. coli* per 100 g of shellfish meat for *E. coli*, the detection level for F+ RNA and absence of detection for EV. The positive level of the threshold was equal to or greater than 230 *E. coli* per 100 g of shellfish flesh for *E. coli*, above the detection level for F+ RNA and positive detection for EV.

The variance estimators for sensitivity and specificity were evaluated using resampling techniques (Efron 1982). Resamples were generated from a nonparametric bootstrap procedure based on the initial samples, consisting of 47 pairs of data for site 1 and 48 pairs of data for site 2 for each organism. Each pair related to the concentration of the organism (*E. coli*, F+ RNA) or the presence/absence of the organism (EV), or the presence/absence of the virus. One thousand replicate samples were generated for each organism based on these data. The mean and variance of both sensitivity and specificity were calculated for the three indicator organisms.

Two conditions were tested for viral contamination. The first concerned all the enteric viruses (V1, i.e., HAV and/or NLV and/or AV and/or RV) except EV, which was used here as an indicator. The other focused on viruses known to be involved in shellfish-borne viral disease (V2, i.e., HAV and NLV). For each condition, a *t*-test at a 95% confidence level was used to compare differences in mean sensitivity and mean specificity between two indicators. Statistical analyses were performed using S-Plus 2000 (MathSoft, Inc., Seattle, WA).

RESULTS

The results obtained throughout the study period for *E. coli* and F+ RNA are shown in Table 2. At site 1, *E. coli* concentrations in shellfish ranged from <30 to 5,670 per 100 g of shellfish, with a geometric mean of 55. At site 2, the maximum value and geometric mean were 20,200 and 283 *E. coli* per 100 g. The F+ RNA content in shellfish ranged between <2.5 and 87 phages per 1.5 g

TABLE 2.

Concentrations (minimum, maximum, and geometric mean) of *E. coli* and F+ RNA in shellfish collected in the study areas.

		E. coli (/100 g of Shellfish)			F+ RNA (/1.5 g of Digestive Tissue)		
	n Analyzed Samples	Min.	Max.	Geometric Mean	Min.	Max.	Geometric Mean
Site 1	47	<30	5,670	55	<2.5	87	3.9
Site 2	48	<30	20,200	283	<5	4,12	46

of digestive tissue with a geometric mean of 3.9 phages per 1.5 g at site 1. Bacteriophage contamination was greater at site 2, with a minimum and maximum of <5 and 4,125, phages per 1.5 g and a geometric mean of 46 phages per 1.5 g. The minimum values obtained at sites 1 and 2 corresponded to the detection limits of the analytical methodology. All enteric viruses except hepatitis A virus at site 1 were found in sampling areas (Table 3). Shellfish were contaminated more often by all types of viruses at site 2 than at site 1.

All *t*-tests comparing mean sensitivity and mean specificity were significant except, at site 1, for the sensitivity results between *E. coli* and EV for V2 (viruses involved in shellfish-borne viral disease, i.e., HAV and VNL). At site 1 (Table 4), F+ RNA had low sensitivity measurements of 0.23 for V1 (all enteric viruses) and 0.50 for V2. This potential viral indicator was associated with viral contamination in only one of five samples for V1 and one of two for V2. The results obtained for *E. coli* and EV sensitivity were lower (0.09 for *E. coli* and 0.13 for EV for V1, and both 0.20 for V2). For V2, the difference in sensitivity between F+ RNA and the other indicators was particularly striking. For specificity, enteroviruses gave the highest estimates (0.92 for V1 and V2) compared to *E. coli* (0.80 for V1, 0.86 for V2) and F+ RNA (0.84 for V1; 0.89 for V2).

The adequacy of the viral indicator relative to viral contamination was greater at site 2 (Table 5) than site 1. Sensitivity estimates ranged between 0.57 (EV) and 0.80 (F+ RNA) for V1 and between 0.73 (EV) and 1.00 (F+ RNA) for V2. The sensitivity of *E. coli* was intermediate, (i.e., 0.66 for V1 and 0.80 for V2). Enterovirus specificities were highest (1.00 for V1 and 0.82 for V2), whereas F+ RNA had the lowest capacity to identify noncontaminated shellfish samples (specificity estimates of 0.33 for V1 and 0.37 for V2). The specificity estimates of *E. coli* were between those calculated for EV and F+ RNA (0.55 for V1 and 0.52 for V2). The sensitivity and specificity estimates for a given candidate were statistically different from those obtained for the others, according to V1 or V2 (*t*-test, 5% in Table 5).

DISCUSSION

The method applied here is currently being used in clinical experiments (Désenclos et al. 1997) to evaluate the accuracy (sensitivity and specificity) of a new screening procedure compared to a gold standard. Sensitivity represents the ratio of individuals classified as "ill" by the method among those known to have the disease, and specificity represents the ratio of individuals classified as "not ill" among those known not to have the disease. These criteria are calculated according to a threshold, and the relative frequency of true-positive (TP), false-negative (FN), false-positive (FP), and true-negative (TN) results depends on the level of this threshold. A low threshold increases sensitivity and reduces specificity, and the opposite is true for a high threshold. The diagnostic strategy requires that sensitivity or specificity be concordant with the objective (avoiding false-negative or false-positive results).

In environmental research, this method was used to compare the validity of *E. coli*, EV and F+ RNA as viral indicators. The purpose of sanitary analysis of shellfish is to provide guarantees that protect consumers from public health hazards due to the consumption of polluted shellfish. In this context, the sensitivity of an indicator is the prime criterion. In other respects, the specificity of an indicator has commercial implications, limiting the period of temporary closure of a shellfish area because of public health concerns. Moreover, sensitivity measurements have greater public health implications in shellfish-growing areas classified as category A sites since these shellfish are consumed directly (without any purification treatment). Accordingly, the following comments are concerned mainly with sensitivity criteria and focused on results obtained for site 1.

No indicator was highly sensitive to viral shellfish contamination in samples from the slightly contaminated area (site 1). Results for F+ RNA sensitivity, though better than those for the other indicators, were not fully predictive of the viral risk related to shellfish consumption. Classification errors were numerous: 50% of the results were FN for viruses involved in shellfish-borne viral disease, V2 (80% FN for all enteric viruses, V1). F+ RNA sensitivity could not be improved because the tested threshold was the detection level of the F+ RNA analytical method (2.5 PFU/1.5 g of digestive tissue for oysters and 5 PFU/1.5 g of digestive tissue for mussels).

Site 1	Sensitivity	Specificity	Sensitivity	Specificity
E. coli	0.09	0.80	0.20	0.86
EV	0.13	0.92	0.20	0.92
F+ RNA	0.23	0.84	0.50	0.89

V1 represents the presence or absence of HAV and/or NLV and/or AV and/or RV; V2 represents the presence or absence of viruses involved in shellfish-borne viral disease (HAV and NLV). All results were significantly different from others (*t*-test, 5%), except for the two 0.20-obtained for V2.

TABLE 5.

Sensitivity and specificity measurements for each indicator organism in site 2 ($n = 48$).

	V1		V2	
Site 2	Sensitivity	Specificity	Sensitivity	Specificity
E. coli	0.66	0.55	0.80	0.52
EV	0.57	1.00	0.73	0.82
F+ RNA	0.80	0.33	1.00	0.37

V1 represents the presence or absence of HAV and/or NLV and/or AV and/or RV; V2 represents the presence or absence of viruses involved in shellfish-borne viral disease (HAV and NLV). All results were significantly different from others (*t*-test, 5%).

The inadequacy of *E. coli* standards for public health protection was confirmed in this study. *E. coli* was the least sensitive and specific tool for identifying samples contaminated by enteric viruses. Enterovirus was not better than *E. coli* in predicting a public health risk, but showed a high degree of accuracy in predicting the absence of viruses, with a low error classification (8% FP). For sporadic contamination, the tested indicators (*E. coli*, EV, and F+ RNA) were not sensitive to the targeted viruses, either because the epidemic cycles were different or because the behavior and survival of the viruses in seawater were variable. Although *E. coli* is part of the bacterial flora of warm-blooded animal feces, F+ RNA phages are an infrequent component of feces. However, these phages are abundant in sewage treatment plants where they proliferate at low temperatures. As they are resistant to various sewage treatment processes and to chlorination, they are more suitable for tracing a sewage effluent than indicating fecal pollution (Havelaar & Pot-Hogeboom 1988, Leclerc et al. 2000). The presence of enteric viruses in sewage water and eventually in coastal water and shellfish is correlated with viral diseases in the general population. Epidemics of viral diarrhea with NLV, RV, and AV etiologies usually follow a seasonal pattern, with a peak in winter (Kapikian et al. 1996, Vinjé et al. 1997, Desselberger 1998, Evans et al. 1998, Otsu 1999). Outbreaks of hepatitis A can occur throughout the year, depending on the different exposure conditions (i.e., contaminated food and water, contact with sewage, travels in endemic countries, direct human transmission) (Hollinger & Ticehurst 1996). Pathologies caused by enteroviruses occur most frequently in summer (Melnick 1996). These epidemiological aspects indicate the difficulty of finding a universal viral indicator.

The sensitivity of all indicators tested was better for samples from the contaminated zone (site 2) than from site 1. As this area is highly affected by urban sewage and is contaminated year-round by fecal coliforms and F+ RNA, these potential indicators could be present systematically when enteric viruses in effluent sewage are discharged into the marine environment during human viral gastroenteritis epidemics. Thus, F+ RNA sensitivity measurements could reach 100%. However, as this area is strictly forbidden for shellfish commercialization on the basis of *E. coli* criteria, a viral indicator would not be more satisfactory than fecal coliforms. These findings are consistent with those already published on marine water contamination in highly contaminated areas (Chung et al. 1998, Legnani et al. 1998).

Concerning areas in compliance with microbiological sanitary criteria, our results differ from those in previous reports recommending F+ RNA as a viral indicator (Chung et al. 1998, Doré et al. 2000), probably because of variations in F+ RNA contamination levels. Moreover, one of these studies (Doré et al. 2000) concerned the use of F+ RNA to evaluate the sanitary quality of market-ready oysters after purification (generally 48 h according to regulations) and not, as in our study, to monitor the water quality in shellfish harvesting areas. During the purification process, the *E. coli* concentration in shellfish is drastically reduced within a 48-h period as compared to phage and virus levels. This short purification period may not be long enough to eliminate viral contamination (Schwab et al. 1998). In such conditions, F+ RNA phages should be reliable indicators of enteric viruses in oysters (Doré et al. 2000).

In a long-term environmental survey, the occurrence and concentration of F+ RNA, as compared to enteric viruses, would probably differ throughout the year. This would be particularly true for slightly contaminated areas in which sewage discharge is sporadic. The F+ RNA results observed in the present study are directly comparable with those of enteric virus detection because both relate to the analysis of digestive gland in which enteric viruses and F+ RNA are mainly concentrated (Atmar et al. 1995, Doré & Lees 1995). Similarly, Croci et al. (2000) found no correlation between enteroviruses, hepatitis A virus, bacteriophages, and *E. coli* in mussels collected in waters in accordance with microbiological sanitary criteria. These authors, as well as Toze (1999), recommended that viruses be detected directly in shellfish to prevent health risks related to their consumption.

Our results indicate that the traditional and proposed indicators tested did not fully prevent the viral risk related to shellfish consumption, especially in slightly contaminated shellfish-growing areas. Direct detection of the real pathogen by molecular tools could provide another means of assessing viral risk for shellfish consumers. This recommendation needs to be considered during high-risk seasons when enteric viruses are likely to be present in the population and enter into wastewater and sewage subsequently discharged into the marine environment (Burkhardt & Calci 2000, Miossec et al. 2000). Further studies are required to confirm these findings.

ACKNOWLEDGMENTS

The authors are grateful to J. C. Sauvagnargues and collaborators (IFREMER) for sampling and bacteriological analyses and to P. Gros (IFREMER) for helpful advice and comments on the manuscript. Financial support was provided by the French Ministry of Environment and the Languedoc-Roussillon Region.

NATURAL OCCURRENCE OF *VIBRIO* SPP. AND *LISTERIA MONOCYTOGENES* IN MOLLUSCAN SHELLFISH IN PORTUGAL

F. S. PEREIRA,* M. M. GUERRA, AND F. A. BERNARDO

CIISA/Laboratório de Inspecção Sanitária, Faculdade de Medicina Veterinária–Universidade Técnica de Lisboa, Rua Prof. Cid dos Santos, Polo Universitário da Ajuda, 1300-477 Lisboa, Portugal

ABSTRACT The natural occurrence of *Vibrio* spp. and *Listeria monocytogenes* in shellfish was analyzed over a period of 18 months. Sixty-one samples of 14 different species of molluscan shellfish were collected in local Lisbon markets (Portugal). *Vibrio* species were detected in 28 shellfish samples (45.9%). Different vibrio species were identified in varying percentages of the shellfish samples tested: *V. parahaemolyticus* (11.4%), *V. alginolyticus* (6.5%), *V. vulnificus* (22.9%), *V. damsela* (9.8%), *V. metschnikovii* (1.6%), and *Vibrio spp.* (21.3%). *Listeria monocytogenes* was isolated from eight samples (13.1%). Other *Listeria* species, *L. innocua* and *L. grayi*, were found in 3.3% and 1.6% of shellfish samples, respectively. *L. monocytogenes* was found simultaneously with other different *Listeria* species in two samples. All *L. monocytogenes* isolates were anti-sera poly O 1–4+. Five samples (8.2% of total) were simultaneously contaminated with *Vibrio* spp. and *Listeria* spp. These results show that *Vibrio* spp. and *L. monocytogenes* are frequently found in shellfish products approved as safe, and the public health significance of these results should not be overlooked.

KEY WORDS: *Vibrio* spp., *Listeria* spp., Portugal, occurrence

INTRODUCTION

Seafood has traditionally been a popular part of the diet in many regions of the world and in some countries, such as Japan, constitutes the main supply of animal protein. Today even more people are turning to fish as a healthy alternative to red meat (Koenig et al. 1991), although there is still some resistance to this habitude. For example, between 1973 and 1987 in the United States, the meat consumption was approximately 10 times that of fish (Huss 1994). This tendency of considering fish as healthy is related to the low fat content of many fish species and the effects on coronary heart disease of the W-3 polyunsaturated fatty acids found in fatty fish species, which are extremely important where cardiovascular disease mortality is high. However, consumption of fish and shellfish has been implicated in many cases of food-borne diseases outbreaks (Huss 1994).

The various disease agents that have been associated with the consumption of seafood may conveniently be divided into two groups: indigenous bacteria and nonindigenous bacteria (Kueh & Chan 1985). *Vibrio* spp. and *Listeria* spp. are included in the mentioned group first (Huss 1994).

Pathogenic *Vibrio* spp. are a human health hazard that occur naturally in estuarine waters. They are frequently found in filter-feeding molluscan shellfish, which are generally the source of infection. Disease resulting from raw oyster ingestion results in fatality rates exceeding 50% for *V. vulnificus* infections (Wittman & Flick 1995, Hlady 1997). The incidence of pathogenic *Vibrio* spp. has been correlated with elevated water temperatures (Kaneko & Colwell 1973, Hlady 1997). Typically, pathogenic *Vibrio* spp. multiply rapidly at temperatures between 20°C and 40°C. This is reflected in the large numbers of the organisms isolated from molluscan shellfish when water temperature rises to 30°C, and their virtual absence from molluses taken from cold waters (ICMSF 1998). For example, *V. parahaemolyticus* is widespread when water temperatures exceed 15°C (Kaneko & Colwell 1973). Nevertheless they also have been isolated from crabs taken from cold waters (ICMSF 1998). *Vibrio* spp. levels in the estuarine environment are also dependent on the time of the day, depth, and tidal levels, and each of those factors must be taken into account to get an accurate estimate of vibrios in the environment (ICMSF 1998). *V. parahaemolyticus*, *Vibrio cholerae*, and *Vibrio vulnificus* are routinely part of the microflora in crustaceans captured from estuarine waters. *Vibrio* species cause a variety of human infections, which can usually be classified as gastrointestinal or extraintestinal infections (Kudoh 1988). Species most commonly associated with diarrhea or gastroenteritis include *V. cholerae* (O1 and non-O1) and *V. parahaemolyticus*. However, *V. fluvialis*, *V. furnissii*, *V. mimicus*, and *V. hollisae* have also been shown to cause or be significantly associated with gastroenteritis (Kudoh 1988, Wittman & Flick 1995). Interestingly, some of these *Vibrio* species may also cause extraintestinal infections such as wound infections and secondary septicemia (Kudoh 1988). *V. vulnificus* is the well-known cause of primary and/or secondary septicemias and wound infections with high mortality. The hazards associated with ingestion of seafood contaminated with this potential pathogen have resulted in a precautionary statement issued by the U.S. Food and Drug Administration against consumption of raw or undercooked seafood by people with hepatic disorders (Anonymous 1992). *V. alginolyticus* and *V. damsela* also cause several types of soft-tissue infections and wound infections. *V. metschnikovii* has been implicated as a cause of opportunistic infections, but its pathogenic significance in the illness needs further investigation. According to Wittman and Flick (1995), between 1984 and 1993, the greatest percentage of known death (95%) due to shellfish-borne disease was caused by noncholera vibrios; noncholera vibrios also accounts for the second highest causative agents of disease.

Fish and seafood are considered potential sources of *Listeria* spp. because this microorganism is ubiquitous in nature (Farber & Peterkin 1991) and salt-tolerant (Dillon & Patel 1992). Fisheries and aquaculture products are directly exposed to water contamination. In fact, *Listeria* spp., and particularly *L. monocytogenes*, have been isolated from a variety of fish and shellfish products (Ben Embarek 1994, Dillon et al. 1992, Dillon et al. 1994, Jørgensen & Huss 1998, Weagant et al. 1988). Although not very involved in listeriosis, the presence of *L. monocytogenes* in seafood and particularly in shellfish has been implicated in some cases. A described epidemic of perinatal listeriosis was related to the consumption of raw fish and shellfish (Lennon et al. 1984), and

*Corresponding author.

some sporadic cases have been identified as associated with shellfish, precisely smoked mussels and raw oysters (Plusquellec et al. 1998). Also a small outbreak of listeriosis associated with smoked mussels has been reported (Brett et al. 1998). To minimize bacterial growth and exposure to this organism, it is important to have adequate control of the environment for food production as well as to take precautions for adequate cooking and handling food (Roberts 1994).

In Portugal, like in many other countries, food-borne diseases are not appropriately reported, thus the epidemiological importance of seafood-borne diseases is lacking. Although some references have been made on the isolation of *L. monocytogenes* in molluscan shellfish in Portugal (Pedro 1996), there is not much information on this subject and the occurrence of *Vibrio* spp. is totally unknown. The consumption of molluscan shellfish is very popular in Portugal, and has increased in the last ten years by 4% (SNI 1997). Additionally, raw or undercooked molluscan shellfish are the favored ways of eating it. The aim of this work was to perform an evaluation of the occurrence of *Vibrio* spp. and *Listeria* spp., particularly *L. monocytogenes*, in molluscan shellfish commercialized in Portugal to obtain some information about the significance of these hazards.

MATERIAL AND METHODS

Samples were collected between March 1998 and July 1999. Fresh molluscan shellfish were obtained from local Portuguese markets and were investigated for the presence of *Vibrio* spp. and *Listeria* spp. A total of 61 samples included three oysters (*Crassostrea angulata*), one hen clam (*Mactra coralina*), five furrow shell (*Scrobicularia plana*), seven mussels (*Mytilus edulis*), seven wedge shell (*Donax trunculus*), six carpet shell (*Tapes decussatus*), seven purr (*Veneropsis corrugata*), two purr (*Veneropsis rhomboide*), seven common cockle (*Cerasthoderma edule*), four periwinkles (*Litorrina littorea*), four whelk (*Buccinnum* sp.), four razor shell (*Solen marginatus*), two cuttlefish (*Sepia officinalis*), and two barnacles (*Pollicipes cornucopia*). All samples were kept below 5°C until arrival at the laboratory, then immediately analyzed. Fifty grams of each sample were suspended in 450 mL of distilled water with 3% NaCl (Merck, Art. 6404) and homogenized for 1 min in a Stomacher (Lab-Blender 400).

For *Vibrio* research, molluscan shellfish were previously washed with a volume of water that was twice its volume in order to detect outer side contamination (shell contamination). This washing water and the homogenized samples were platted on thiosulphate citrate bile sucrose agar (TCBS) (Oxoid CM333) and incubated at 37°C for 24 h to determine the levels of *Vibrio* spp. without a previous enrichment. A selective enrichment was also performed in alkaline peptone water (Oxoid CM9), incubated at 37°C for 24 h, followed by plating on TCBS. After incubation at 37°C for 24 h, the presumptive colonies, sucrose-negative and sucrose-positive, were confirmed by their sensibility to the vibriostatic compound 0:129 (Oxoid DD14 and DD15) and biochemically identified by Api 20NE (Bio-Mérieux 20050) and Api 20E (Bio-Mérieux 20100). Colonies not identified to species were designated *Vibrio* spp.

Isolation of *Listeria* spp. was performed using a nonselective enrichment broth, buffered peptone water (BPW) (Oxoid CM 509). After 24 h of incubation at 30°C, 1 mL was transferred to both 10 mL of enrichment Fraser Broth (Merk 110398) and thioglycollate medium U.S.P. (Oxoid CM173). A selective enrichment procedure was performed after 24 h at 30°C by transferring 1 mL of each previous enrichment to both 10 mL of University of Vermont Medium with supplement 1 (UVM I) (Oxoid CM863 and SR142) and Fraser Broth (Merk 110399) with half-strength supplement (Merk 110399).

Plating on selective medium, Palcam agar (Oxoid CM8719, SR150E) and McBride agar (Difco 0922-17), followed both nonselective and selective enrichment procedures after incubation at 30°C for 24 h and 30°C for 48 h, respectively. Palcam agar plates were incubated at 30°C for 24–48 h and McBride agar plates at 37°C for 24–48 h. Four or five presumptive colonies of each plate were subcultured for purity on Tryptone-Soya Agar (Oxoid CM131) with 0.6% of yeast extract (Difco 0127-01-7).

Identification of the isolates was performed using conventional tests: catalase and oxidase test, Gram reaction, and observation of bacterial morphology. Tumbling motility at 25°C was observed, and respiratory type and umbrella motility were tested on SIM medium (Oxoid CM435). CAMP test and the production of β-hemolysis was performed on Columbia agar plus 5% sheep-blood (BioMérieux 43 041). Api *Listeria* strips (BioMérieux 10 300) were used for biochemical identification (Fig. 1). Serological tests were performed using *Listeria* O antiserum poly serotypes 1, 4 (Difco Laboratories, Detroit, MI).

RESULTS

Vibrio spp. were isolated from 31 of the 61 samples (50.8%). From the 14 different species of molluscan shellfish studied (Table 1), *Vibrio* spp. were found in all species, except one, *Mactra coralina*. Five different species of *Vibrio* were identified: *V. parahaemolyticus*, *V. vulnificus*, *V. alginolyticus*, *V. damsela*, and *V. metschnikovii*. *V. parahaemolyticus* was found in *M. edulis*, *T. decussatus*, *V. corrugata*, *V. rhomboide*, *C. edule*, *L. littorea*, and *Buccinum sp.* *V. vulnificus* was found in *C. angulata*, *M. edulis*, *D. trunculus*, *T. decussatus*, *V. corrugata*, *C. edule*, *L. littorea*, *Buccinum* sp., *S. marginatus*, *S. officinalis*, and *P. cornucopia*. *V. alginolyticus* was found in *D. trunculus*, *C. edule*, *Buccinum* sp., and *S. officinalis*. *V. damsela* was found in *D. trunculus*, *C. edule*, *Buccinum* sp., *S. marginatus*, and *S. officinalis*. *V. metschnikovii* was found in *V. corrugata* (Table 2). The highest levels found were for *V. parahaemolyticus* ($10^{2.3}$ cfu/g) in *V. rhomboide* and *L. littorea*, and *V. alginolyticus* ($10^{2.3}$ cfu/g) in *D. trunculus* and *C. edule*, followed by *V. metschnikovii* (10^{2} cfu/g) and *V. vulnificus* ($10^{1.8}$ cfu/g), both in *V. corrugata*. The highest levels of contamination were found in the inner tissue of the shellfish (Table 2).

V. vulnificus was found all through the year, even during the cold months of winter (November, January, and February). On the other hand, *V. parahaemolyticus* was only found in warmer months of May, June, and October. *V. alginolyticus* and *V. damsela* were also found all through the year (Fig. 1).

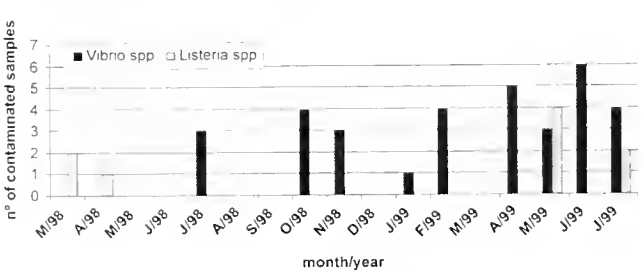

Figure 1. Number of samples contaminated with *Vibrio* spp. and *Listeria* spp. in monthly samples: March 1998 to July 1999.

TABLE 1.

Frequency of *Vibrio* spp. and *L. monocytogenes* in Portuguese molluscan shellfish.

Shellfish Species	*n*	*Vibrio* spp. N+ (%)	*Listeria* spp. N+ (%)	*Vibrio* spp. and *Listeria* spp. N+ (%)
Crassostrea angulata	3	1	0	0
Mactra coralina	1	0	1	0
Scrobicularia plana	5	1	1	0

Sepia officinalis	2	2	0	0
Pollicipes cornucopia	2	1	1	0
Total	61	31 (50.8%)	9 (14.8%)	5 (8.2%)

Listeria spp. was isolated in 9 of the 61 samples (14.8%) (Table 1). The contaminated samples were: *C. edule* (two), *M. edulis* (two), *M. coralina* (one), *S. plana* (one), *P. cornucopia* (one), *S. marginatus* (one), and *Buccinum* sp. (one). Different species of *Listeria* were isolated. *L. monocytogenes* was the most frequent, found in eight samples (13.1%), whereas *L. innocua* was found in two samples (3.3%) and *L. grayi* in one sample (1.6%) (Table 3). *L. monocytogenes* was found concomitantly with other *Listeria* species in two samples, once with *L. innocua* and *L. grayi* in *M. coralina* and once with *L. innocua* in *M. edulis*. All *L. monocytogenes* isolates were anti-sera poly O 1–4+. Five samples (8.2%) were simultaneously contaminated with *Vibrio* spp. and *Listeria* spp. (Table 1).

DISCUSSION

Since *Listeria* spp. are ubiquitous and *Vibrio* spp. are naturally occurring in the aquatic environment, their reported prevalence is not surprising. Moreover, shellfish filter large quantities of water and therefore are able to concentrate water-borne pathogens including some *Vibrio* spp. and *L. monocytogenes* (NACMCF 1992).

The *Vibrio* spp. levels associated with the outer side of the shellfish suggests that shellfish manipulation as well as cross-contamination with *Vibrio* can also be a hazard (Hobbs & Roberts 1987). Contamination levels show that *Vibrio* spp. can be an important hazard in molluscan shellfish safety because many outbreaks are due to consumption of raw seafood that may be naturally contaminated with small numbers of *Vibrio* spp. but are held unrefrigerated long enough to allow organisms to proliferate to large numbers. Outbreaks involving boiled shellfish have been attributed to failure to cook the shellfish at temperatures high

TABLE 2.

enough to kill *Vibrio* spp. Other outbreaks have been attributed to contamination of cooked seafood by raw seafood followed by inadequate refrigeration (Blake et al. 1980, Hobbs & Roberts 1987). The levels from the inner tissue of the animal are lower than the ones reported previously from molluscan shellfish collected in Hong Kong markets that ranged between 10^4 and 10^5 cfu/g (Chan et al. 1989). This might be due to the lower temperatures of the seawater in Europe (between 13°C in winter and 22°C in summer). On the other hand, it is known that enrichments plated on CPC agar are more appropriate for *V. vulnificus*, as well as including the addition of polimixin to the enrichment medium (Dalsgaard & Hoi 1997). This might explain the lower levels obtained once the initial research procedures were performed with nonspecific culture media. However, media designed for one vibrio could delay or inhibit the growth of other *Vibrio* species. The incidence of *V. vulnificus*, *V. alginolyticus*, and *V. damsela* was not characterized by a seasonal distribution, probably due to the low temperature amplitudes in Portuguese seawater. On the other hand, *V. parahaemolyticus* was isolated only during the warmer months.

Listeria-contaminated samples were collected on March and April 1998 and May and July 1999 (Fig. 1), which reveals the tendency of this microorganism to develop in warmer temperatures (Dillon and Patel 1992). In a previous study conducted in Portugal, Pedro (1996) isolated *Listeria* spp. and *L. monocytogenes* in 23% and 20%, respectively, of samples from 35 shellfish. Isolations were only performed on clams and furrow shells. These results and this study's results obtained in Portugal reveal some differences when compared with those cited in literature where the presence of this microorganism is mostly found in oysters and mussels. de Simón et al. (1992) found *Listeria* spp. in 22.5% of the 40 samples of mussels analyzed and detected *L. monocytogenes* in three of them (7.5%). These authors also isolated *L. innocua* and *L. seeligeri* in 12.5% and 2.5% of the mentioned samples, respectively. In oysters, Weagant et al. (1988), Buchanan et al. (1989), and Colburn et al. (1990) did not find *Listeria* in any seafood sample. Motes (1991) did not find *Listeria* spp. from 75 oysters samples, all collected from estuarine environments along the U.S. Gulf Coast. Wilson (1995) isolated *Listeria* spp. in 11.0% of the molluscan/crustacean samples analyzed (8/74) in Ireland. In Finland, Hartemink and Georgsson (1991) found *Listeria* spp. in samples of raw and smoked fish, but no isolation was made in 11 shellfish samples. Jeyasekaran et al. (1996) isolated *Listeria* spp. in 44.4% (16/36) of shellfish samples in India, and *L. monocytogenes* was found in 12.1% of the contaminated samples. These authors also isolated *L. innocua* and *L. welshimeri* in 36.1% and 5.6% of the tropical samples, respectively.

In our study, *L. monocytogenes* was the predominant species (13.1%) and *L. innocua* the second most common (3.3%). In the literature *L. innocua* is seldom referred to as being the most commonly isolated species (Weagant et al. 1988, Ryu et al. 1992, Wilson 1995, Jeyasekaran et al. 1996). This fact is related to the shorter generation time of *L. innocua* in enrichment broth, which may lead to false-negative *L. monocytogenes* results in cultures where the two species are both present (Petran & Swanson 1993, Curiale & Lewus 1994). On the other hand, the coexistence of these two species in some samples (Table 3) indicates that these microorganisms may share the same ecological niche. Furthermore, the presence of nonpathogenic *Listeria* spp. is considered to be an "indicator" of the presence of the pathogenic species (King et al. 1989). The nonselective enrichment step followed by a selective enrichment in two different media might have contributed to the slight enhancement of *L. monocytogenes*, because it constitutes a resuscitation step that may favor its recovery. This procedure has been recommended especially when examining products where *Listeria* spp. cells are expected to be injured (McCarthy et al. 1990).

Vibrio spp. and *Listeria* spp. were isolated simultaneously in five samples. These results have never been reported in Portugal. The analysis of the epidemiology of some food-borne diseases reveals a significantly higher rate of coinfection in patients due to naturally occurring pathogens (Hlady 1997). Hence, these results suggest the possibility of a higher risk with the consumption of these particularly molluscan shellfish.

Considering the direct utilization of molluscan shellfish in human diet and the deficient cooking habits applied to shellfish, *L. monocytogenes* and *Vibrio* spp. occurrence must be regarded as a relevant hazard to public health. Therefore, due to the importance of seafood on the Portuguese alimentary habits, it would be important to establish the real hazards to humans.

THE PREVALENCE OF NONCULTIVABLE BACTERIA IN OYSTERS (*TIOSTREA CHILENSIS*, PHILIPPI, 1845)

JAIME ROMERO AND ROMILIO ESPEJO*

Laboratorio de Bioingeniería, Instituto de Nutrición y Tecnología de los Alimentos, Universidad de Chile, Macul 5540, Santiago, Chile

ABSTRACT Genotypic analysis based on molecular methods has become a useful tool to determine the composition of bacterial populations and communities. We used this tool to study the microflora of oysters. Analysis of the electrophoretic mobility of the 16S–23S rDNA spacers of the bacteria, isolated from oysters and cultured in marine agar, revealed the presence of three main groups of bacteria. Within each group the bacterial strains had identical 16S rDNAs, as judged by the electrophoretic mobility of the heteroduplexes formed between amplified 16S rDNA. The extrapolation of these findings to the total bacterial population, however, seems unwarranted because the number of colonies grown in agar was less than 0.001% of the bacteria present in the oysters. Consistently, the electrophoretic mobility of the 16S–23S rDNA spacers of the total bacterial DNA extracted from oysters had a very different pattern of that extracted from the bacterial cultures. Analysis of bacterial DNA obtained from individual oysters showed the presence of some spacers in most of the oysters examined. These spacers may belong to bacteria of a common microflora that are noncultivable in marine agar. We conclude that most bacterial strains present in oysters are not cultivable in marine agar.

KEY WORDS: microflora, noncultivable bacteria, oyster, intergenic spacer

INTRODUCTION

Animals harbor large, active, and complex communities of microbes. Among them is the normal microflora, a population of microbes that despite its continual contact with different tissues causes no harm to the host. On the contrary, the normal microflora may have beneficial effects. It may participate in the host nutrition by complementing the process of food digestion or by contributing to the metabolism of endogenous and exogenous compounds. Normal microflora may also play a role in pathogenesis by preventing the host colonization by pathogens, controlling their growth, and modulating the immune response of the host. The composition of each particular microflora is probably determined by host properties, such as its contact history with colonizing bacteria and the dietary and environmental conditions that prevail in its habitat (Kirjavainen & Gibson 1999, Savage 1986).

At harvest oysters normally contain 10^3 to 10^5 CFU/g (De Paola et al. 1990, Wright et al. 1996), which may consist of either normal microflora or bacteria present in recently ingested food (Cook 1991, Vanderzant & Thompson 1973) or both. Bacterial flora in oysters has been described by phenotypic characterization of the strains isolated by culture, usually in marine agar (Colwell & Liston 1960, Murchelano & Brown 1968). *Vibrio* and *Pseudomonas* spp. are the bacterial species most frequently isolated from oysters. They account for 20–30% of the total CFU found in these bivalves (Colwell & Liston 1960, Murchelano & Brown 1968, Kueh & Chan 1985). The load of vibrios in the oyster's normal microflora varies according to several factors including the environmental temperature (Kaspar & Tamplin 1993) and the oyster health status (e.g., the presence of parasites) (Tall et al. 1999). Among the vibrios, important human pathogens such as *V. vulnificus* and *V. parahaemolyticus* are occasionally found in oysters (Motes et al. 1998, Kaspar & Tamplin 1993, De Paola et al. 1990, Cook 1994, Wright et al. 1996). However, since the only bacterial microflora thus far characterized in oysters is that able to grow in conventional culture media, it is likely that important strains unable to grow in such media have been missed by this kind of analysis. This situation has been described in many different bacterial habitats (Amman et al. 1995, Ueda et al. 1999, Suau et al. 1999). An example of a noncultivable bacteria found in oysters is *Cristispira pectinea*, a large spirochete that is commonly identified by its shape and large size in the crystalline style (Paster et al. 1996, Margulis et al. 1991).

The availability of methods for the detection and genetic characterization of bacteria irrespective of the microorganism's ability to grow in culture media offers the opportunity to better characterize the bacterial microflora of different animal species including the oyster (Amman et al. 1995). Two of the most commonly used methods for genetic characterization of bacterial communities are the analysis of the nucleotide sequence of 16S rDNAs (Schmidt et al. 1991) and the study of the size of the spacers found between the 16S and 23S rRNA genes (Gurtler & Stanisich 1996, Jensen & Straus 1993). This last method, though less informative, is easier to perform. The size pattern of the bacterial spacers in the community is obtained by PCR amplification of DNA extracted directly from the sample and subsequent gel electrophoresis. The pattern obtained allows for comparisons and observation of changes in the bacterial community composition. On the other hand, the nucleotide sequences of specific 16S rDNAs can be easily compared by the heteroduplex mobility assay (HMA). This assay is based on the fact that the heteroduplexes with unpaired single-stranded regions (formed as a result of the annealing of not fully complementary nucleic acid strands) display a decreased electrophoretic mobility relative to that of homoduplexes formed between identical DNA strands (Espejo et al. 1998).

Increased knowledge of the bacterial ecology of oyster microflora would greatly help the understanding of the role of bacterial microflora in digestion, metabolism, and protection from pathogens. It would also help to improve oyster management at hatcheries to avoid their colonization by pathogens to both oysters and humans. As an initial step toward the understanding of the oyster bacterial ecology, we describe here the bacterial community found in oysters according to the molecular analysis of their DNA. Results obtained from bacteria cultured in marine agar as well as those derived from bacteria directly obtained from the oysters are described.

MATERIALS AND METHODS

Oyster Homogenate Preparation

Live oysters (*Tiostrea chilensis*) from the Quinua hatchery, Calbuco, Chile were used in our studies. Oysters in good condition, with tightly closed shells, were processed 6 h after harvest. The oysters were shucked, weighed, and an equal amount of cold sterile TEx10 (0.1 M Tris, 0.01 M ethylenediamine-tetraacetic acid) and 0.15 M NaCl (pH 7.8) was added. The oysters were subsequently homogenized in an ice bath with a Tissue Tearor (TM, model 985-370, Biospec Products Inc., WI, USA) at maximum speed for 3 min.

Culture Methods

To obtain the total cultivable bacterial count, oyster homogenates were serially diluted in 1% NaCl and plated onto marine agar. Plates were incubated for three days at 17°C (Collins et al. 1991). Putative human pathogens of the genera vibrio were detected with an enrichment protocol with alkaline peptone water (APW). Homogenate samples diluted 1:10 in APW (0.5 mL of sample in 4.5 mL of APW) were incubated without shaking for 16 h at 37°C. After enrichment, samples were plated on thiosulfate citrate bile salt sucrose (TCBS) agar and incubated for 48 h at 37°C (Wright et al. 1996).

Total Bacterial Count

Diluted homogenates were dually stained with a combination of DAPI (final concentration 5 μg/mL) and AO (final concentration 1 mg/mL) for counterstaining as described by Kuwae and Hosokawa (1999). Bacterial cells were observed using epifluorescence microscopy.

DNA Extraction from Oysters

After testing different procedures, the following DNA extraction method was adapted. The oyster homogenates were diluted (8% w/v) in TEx10/0.15 M NaCl and sodium dodecyl sulphate (SDS) was added to a final concentration of 1%. The mixture was heated at 70°C for 20 min, vigorously vortexed, and then centrifuged at 10,000 × *g* for 5 min. The supernatant was first extracted with phenol and then with a mixture phenol:chloroform (1:1). After centrifugation, the DNA in the aqueous phase was precipitated with ethanol, resuspended in sterile distilled water, and treated with RNAse A (100 ug/mL). Solid ammonium acetate (ca. 0.1 g/200 μL) was then added for a final concentration of 3 M. The samples were vortexed and centrifuged at 16,000 × *g* for 15 min, and then the DNA in the supernatant was extracted with an equal volume of chloroform:isoamyl alcohol (24:1). The DNA in the aqueous phase obtained after centrifugation was precipitated with 0.6 volumes of ice-cold isopropanol, washed once with 70% ice-cold ethanol, dried under vacuum, and then resuspended in sterile distilled water. DNA was further purified by incubation with Chelex (Bio Rad) 1% at 56°C for 30 min and then boiled for 5 min. Dilutions of supernatant were used as template for amplification.

DNA Extraction from Colonies

Marine agar plates containing 30–50 colonies were washed twice with 5 mL of cold sterile TEx10/0.15 M NaCl. The suspension was lysed with 1% SDS and DNA was extracted as described above.

Amplification Using a Single Colony as Template

Isolated strains were streaked onto marine agar and single colonies were resuspended in TE pH 8.0. Suspensions were boiled for 30 min and then centrifuged at 5,000 × *g* for 15 sec. Dilutions of the supernatants were subsequently used as templates for amplification.

PCR Amplification of 16S rRNA Genes and 16S–23S rRNA Spacers and HMA Analysis

16S rRNA genes were amplified by PCR and analyzed by HMA as described by Espejo et al. (1998). In brief, 16S rDNA in different combinations were denatured and reannealed and the electrophoretic mobility of the homoduplex and the heteroduplex was determined by polyacrylamide gel electrophoresis. The 16S–23S rDNA spacer regions were amplified by PCR and analyzed by size as described by Pizarro et al. (1996).

RESULTS

Cultivable Bacteria

Bacteria present in oysters were initially analyzed after cultivation. The oysters were obtained from a hatchery located at 40° latitude south, where the water temperature oscillates between 12°C and 14°C year-round. Two homogenates of six oysters each, harvested in August and October, rendered 10^3 and 10^5 CFU/g, respectively, when plated on marine agar. No putative pathogenic vibrio strains were observed when plated in TCBS incubated at 37°C. The genetic diversity among the bacterial colonies grown in marine agar was assessed by comparison of the sizes of their intergenic spacer regions located between the 16S and 23S rRNA genes. Of the 17 colonies obtained on marine agar (October sample), 80% were grouped into three clusters, designated A, B, and C according to the overall band pattern and the presence of common bands (Fig. 1). Group A had eight strains and was characterized by the presence of two bands of about 500 and 850 base pairs (bp), respectively. Group B had four strains and was characterized by the presence of an intense band of approximately 400 bp. Group C, in turn, had four strains and presented a band pair of about 450 and 470 bp. Pattern similarity and the number of bands in each group were variable. Group A was the most homogeneous

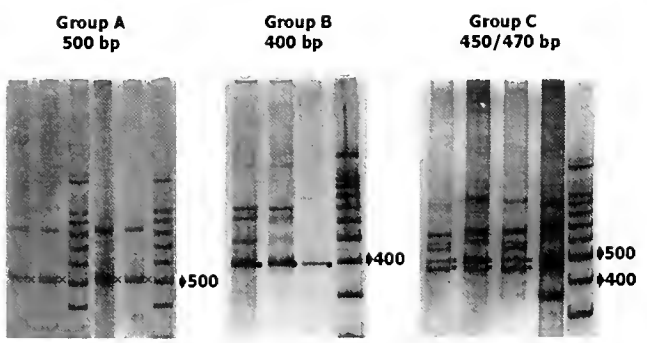

Figure 1. Polyacrylamide gel electrophoresis of the 16S–23S spacers obtained by PCR amplification of DNA from single colonies. Colonies are grouped according to the pattern of the observed spacers. X indicates the main spacer 500 bp observed in group A, ● indicates the main spacer 400 bp in group B, and * indicates the main spacer pair 450/470 bp in group C.

and group C the least. In addition, group C yielded the largest number of bands after amplification.

Cultivated strains assigned to the different groups according to their 16S–23S rDNA spacers were compared within and between groups by HMA analysis. The sequence similarity of the 16S rDNAs obtained from the different colonies following amplification was estimated by the migration of the heteroduplexes formed after denaturation and reannealing of different combination of samples. Analysis of strains belonging to groups A and B showed that within each group heteroduplexes with a slightly retarded migration were formed (Fig. 2A, lanes A1/A2 and B1/B2). This indicates that the 16S rDNAs of the bacterial strains within each of these groups were practically identical. On the other hand, hybridization between strains from groups A and B resulted in the formation of heteroduplexes with a significantly retarded migration (Fig. 2A, lane B1/A2). According to previous results (Espejo et al. 1998), this retarded migration would correspond to a nucleotide sequence difference of 15–20%. Amplification of 16S rRNA of every strain from group C rendered two products with different migration patterns (Fig. 2B, lanes C1/- and -/C2) indicating the presence of heteroduplexes. The heteroduplex nature of the slower migrating band observed in these cases was demonstrated by its disappearance after a single round of amplification following dilution (results not shown). As previously shown, dilution prevents annealing of the amplification products during the annealing step of the amplification cycle and hence formation of heteroduplexes (Espejo et al. 1998). The finding that 16S rDNAs with different sequences were obtained from a single colony was somewhat surprising but not completely unexpected. While a single colony is normally expected to contain only 16S rDNA genes with the same sequence, examples of intracellular heterogeneity of 16S rDNA are increasing (Ueda et al. 1999). On the other hand, analysis of the mobility of heteroduplexes formed between strains of bacteria of group C revealed differences in sequence similar to those observed upon amplification of a single strain (lane C1/C2). This indicates that the sequence differences of the 16S rDNAs within a single colony are comparable to the differences found between the 16S rDNAs of different bacterial strains of this group. Instead, the heteroduplexes formed between strains of group C and strains of either group A or B displayed a much slower migration compatible with a sequence difference of about 15% among these groups (lanes A1/C2, B1/C2).

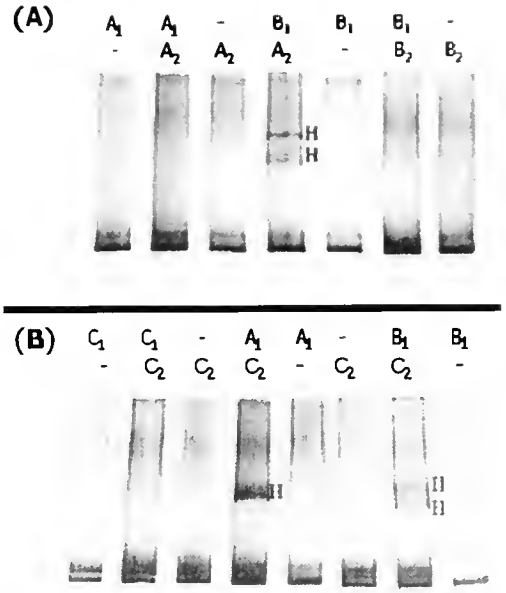

Figure 2. Sequence similarity between 16S rDNAs obtained from colonies with different 16S–23S spacer pattern estimated by HMA. The letters on the top of each lane indicate the group of the colony from which the 16S rDNA was amplified. The number identifies the colony. - indicates absence of a second 16S rDNA. H next to some bands indicates the heteroduplexes.

Noncultivable Bacteria

The bacteria characterized above seem to correspond to a small fraction of the total bacteria present in the oyster. Microscopic observations after DAPI/AO staining of the homogenates obtained from a pool of six oysters harvested in October indicated the presence of about 10^{10} bacterial cells per gram, 10^5 times more than those observed by plating. A comparison was made between the composition of the total bacteria and that of the bacteria obtained after cultivation, through the comparison of the spacer patterns observed after amplification. DNA extracted from both oyster pools and bacterial cultures was amplified and spacers resolved by polyacrylamide gel electrophoresis (Fig. 3). The patterns obtained from each preparation were very different, suggesting that the bacterial community cultured in marine agar is very different from the total bacterial population present in the oysters. The main bands observed in the amplification product of the DNA extracted from the oysters were not observed in the amplification product of the DNA extracted from the mixture of colonies recovered from the marine agar culture plates. The absence of these bands suggests, in agreement with the previous observation, that very few of the most abundant bacteria present in the oysters were able to form colonies in marine agar.

16S–23S rDNA Spacer Pattern in Individual Oysters

Since very few of the bacteria present in the oysters were able to grow in marine agar, we decided to analyze the composition of

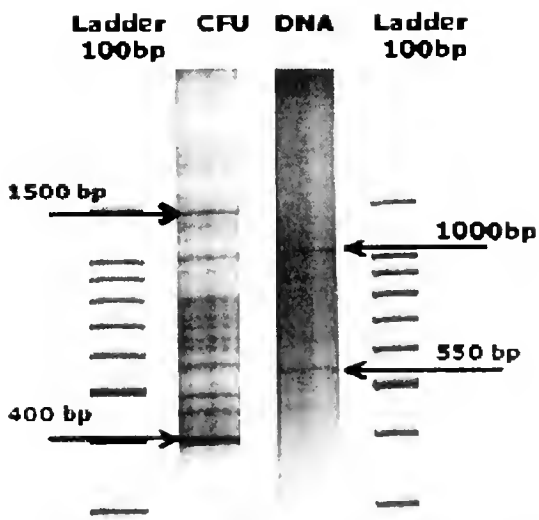

Figure 3. 16S–23S rDNA spacer pattern observed after PCR amplification of DNA extracted from the colonies grown in marine agar plates (CFU) and directly from the oyster pool (DNA). Arrows indicate the position and size of the main spacers observed in each sample.

bacteria of individual oysters by amplification of DNA extracted directly from the oysters without prior cultivation. The premise behind the idea of analyzing individual oysters was that those strains belonging to the normal microflora should be present in most of the oysters. DNA was extracted from six individual oysters and the patterns of the 16S–23S spacers, obtained after amplification, were compared. Despite the fact that different individuals had different spacer patterns, some spacers with similar migrations were present in most of the oysters. Three specific spacers were readily observable in four of the six oysters, though in different proportions (Fig. 4A). Their approximate sizes were 1000, 550, and 450 bp. In addition, the 550- and 450-bp spacers were present in six and five of the oysters, respectively. Furthermore, the 1,000- and 550-bp spacers were also detected in pooled samples of DNA obtained from the homogenates prepared from oysters harvested both in October and August (Fig. 4B).

DISCUSSION

Increased knowledge on the bacterial ecology of the oyster microflora would greatly contribute to the understanding of the role of bacterial microflora on the host digestion, metabolism, and protection from pathogens. This knowledge may be applied to hatchery management and also to postharvest processes to improve oyster quality and safety. A first requisite to ecological studies is a comprehensive knowledge of the community composition. Our results show that, as it has been observed in many other marine habitats (Amman et al. 1995), the bacteria obtained after cultivation represent only a minor fraction (<0.001%) of the total bacterial population present in the oysters. This recovery is one of the lowest reported in marine habitats (Amman et al. 1995, Schmidt et al. 1991). While the reason for this low recovery is not known, it is possible that a large part of the total bacterial count included nonviable microorganisms such as ingested allochthonous bacteria inactivated by the oyster digestion process. On the other hand, the absence of cultivable putative pathogenic vibrios, those able to grow at 37°C, may be due to the low coastal water temperature in this region (12–14°C year-round) as it is known that the presence of cultivable vibrio is greatly diminished at low temperature (Kaspar & Tamplin 1993, Motes et al. 1998). We cannot disregard, however, their presence in a viable noncultivable state as it has been described in some pathogenic *Vibrio* spp. like *Vibrio vulnificus* (Oliver 1995) and *Vibrio parahaemolyticus* (Jiang & Chai 1996).

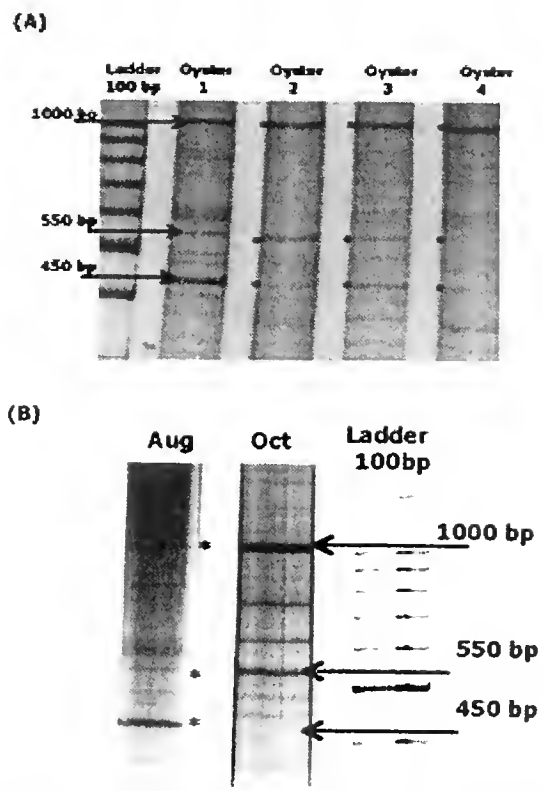

Figure 4. 16S–23S rDNA spacer observed after amplification of DNA extracted from individual oysters (A) and from pools of six oysters harvested in August and October 1999 (B). The results of only four oysters are shown (lanes oysters 1–4). Arrows and asterisks indicate the position and size of three spacers observed in most of the individual examined.

Cultivable bacterial strains may not only represent a minute fraction of the total number but also of the diversity of the microorganisms present in these bivalves. Detailed phenotypic or genotypic analysis based exclusively on the study of the bacterial community obtained after culturing seems to be of little value for a general understanding of the bacterial ecology in oysters. This does not imply that the results obtained from studies using cultivated bacteria are worthless. This type of study does give information about bacteria actually present in the hosts of study. Its limitation, however, is one of lack of generalizability. A more complete understanding can certainly be obtained from studies that combine both the analysis of cultivated bacteria as well as that of bacteria directly obtained from the host without prior cultivation.

Bearing in mind the limitation of culture studies, our results with cultured bacteria provide interesting information regarding the genetic features of these strains. The fact that most of the cultured bacteria could be grouped in three clusters according to the overall band pattern and the presence of common bands indicates that these three groups may prevail among the cultured strains. The high sequence similarity of the 16S rDNAs within the same spacer group and the dissimilarity observed between groups suggests that spacer patterns may be a useful tool to distinguish species in the oyster ecosystems. Interestingly, strains in group C showed the largest intragroup heterogeneity in spacer patterns and rendered more than one band after amplification of their 16S rDNA. As previously shown, these bands correspond to heteroduplexes formed during the last cycle of amplification by annealing between single strands of different sequences (Espejo et al. 1998). These heteroduplexes are probably due to the presence of 16S rDNAs differing in sequence. Our results add to the increasing number of reports of intracellular heterogeneity in 16S rDNA (Ueda et al. 1999).

According to the results obtained with cultured strains, the observation of particular spacers may be used as indication of the possible presence of specific bacterial strains. Considering that cultured bacteria correspond to such a low fraction of the total bacteria present in oysters, the large differences in the spacer patterns observed between bacterial DNA extracted from oysters and DNA obtained from cultured bacteria is not surprising. This large difference suggests that the groups of microorganisms observed after cultivation in marine agar do not represent the prevailing bacteria of oysters.

The spacer patterns obtained from individual oysters indicate the presence of a complex and different community of microorganisms in each individual. However, the spacers common to most

of the oysters analyzed (corresponding to approximate sizes of 1,000, 550, and 450 bp) may correspond to bacterial strains that constitute part of the normal oyster microflora and as such are present in most individuals. The apparent presence of these same spacers in pools of oysters harvested at different times of the year also supports this hypothesis. These spacers would correspond to bacteria unable to grow in marine agar because they are not observed after amplification of the DNA obtained from the cultured bacteria.

These results are similar to those obtained on the human intestinal microflora, one of the most extensively studied microbial habitats. Intestines contain 10^{10} to 10^{11} CFU/g with an overall composition that differs among individuals but that may be stable for months in the same person (Zoetendal et al. 1998). Some bacterial species appear to be present in most individuals and are considered part of the normal microflora (Zoetendal et al. 1998, Moore & Moore 1995, Matsuki et al. 1999). Many of these species can only be detected through direct DNA analysis because it has not been possible to culture them (Suau et al. 1999). In the abovementioned studies, however, the fraction of cultured bacteria is much larger than in our study.

The variations in the composition of normal microflora between individuals due to environmental and dietary differences are likely to be less pronounced in oysters than in human beings. Oysters grow in a much more homogeneous environment, which makes it more likely that they share the same diet and consequently similar microflora.

Our results suggest that in oysters there are some bacterial strains that may form part of the normal microflora. These strains, however, are not observed when the bacteria are cultured in marine agar, as is commonly the case. For an appropriate and comprehensive description of the microflora, needed for understanding the bacterial ecology in oysters, it is necessary to distinguish between bacteria of the normal microflora and allocthonous bacteria, such as opportunistic bacteria or those ingested with food. We plan to accomplish this by examination of the prevailing spacers after depuration of the oysters to remove opportunists and ingested bacteria. Once the putative normal microflora has been defined, cultivation of the bacteria containing the main spacers will be attempted using specially designed media and different culture conditions. Successful cultivation will be necessary to accomplish the phenotypic identification of the bacteria constituting the normal microflora of oysters.

ENTERIC VIRUS CONTAMINATION OF SHELLFISH: INTERVENTION STRATEGIES

GARY P. RICHARDS

United States Department of Agriculture, Agricultural Research Service, Delaware State University, W.W. Baker Center, Dover, Delaware 19901

ABSTRACT Enteric viruses, such as hepatitis A, Norwalk-like caliciviruses, rotaviruses, and astroviruses, are responsible for outbreaks of food-borne illness. There are an estimated 9.2 million cases of food-borne Norwalk-like illness in the United States each year. The portion of those cases associated with shellfish is uncertain; however, shellfish are a major vector of human caliciviruses. In addition to the classical viral illnesses transmitted by shellfish, hepatitis E may become a potential threat to the shellfish consumer, particularly in Asian countries. Intervention strategies to enhance product safety include increased industry and consumer education; changes in harvesting and water monitoring practices, product management, and processing technologies; immunizations; and the development of improved detection methods.

KEY WORDS: enteric virus, hepatitis, Norwalk, rotavirus, astrovirus, illness, shellfish, intervention

INTRODUCTION

Enteric viruses encompass a broad spectrum of pathogens transmitted to food and water by the fecal-to-oral route. They include hepatitis A and E viruses, Norwalk and related caliciviruses, rotavirus, astrovirus, enteric adenovirus, and coronavirus. Molluscan shellfish are filter feeders capable of bioconcentrating viruses that are present in seawater within their edible tissues. Data on the incidence of enteric virus illness in the United States were compiled by the Centers for Disease Control and Prevention and indicate that 23 million people in the United States contract Norwalk-like viral illnesses each year, 40% of which are food-borne (Mead et al. 1999). In addition, 3.9 million people develop rotavirus and astrovirus infections, and 83,000 people develop hepatitis A (Mead et al. 1999). Only 1% of the astrovirus and rotavirus infections and 5% of the hepatitis A cases are estimated to be from foods (Mead et al. 1999). The number of illnesses caused by the ingestion of molluscan shellfish is uncertain, but shellfish are likely to be a major contributing factor for Norwalk virus illness and perhaps for hepatitis A as well. Outbreaks of hepatitis A and Norwalk-like illnesses have been linked to shellfish consumption (Richards 1988, Halliday et al. 1991). A major outbreak that was associated with the consumption of clams obtained from a mud flat outside of Shanghai, China, occurred in 1988, causing over 292,000 cases of hepatitis A over a three-month period (Halliday et al. 1991). Norwalk virus caused close to 1,500 oyster- and clam-associated illnesses in New York and New Jersey in 1982 (Richards 1985).

To date, only sporadic cases of hepatitis E have been identified; however, hepatitis E is a major cause of morbidity and mortality in Asia and may eventually spread throughout the world. In the general population, hepatitis E has a mortality rate of 0.5–3% of the individuals infected; however, the death rate is substantially higher (15–25%) in pregnant women (Mast & Krawczynski 1996).

CHARACTERISTICS OF ENTERIC VIRUSES

Human enteric viruses are only known to replicate in human and some primate cells; there is no replication in shellfish. Therefore, there is no virus amplification within foods and temperature abuse does not increase virus numbers. Within the environment, viruses may persist for weeks or months and once in shellfish may last for several weeks (Gerba & Goyal 1978). They may be preserved by cold temperatures and may be infectious in very low numbers. As few as 10–100 virus particles may be sufficient to elicit an infection (Cliver 1997).

SOURCES OF CONTAMINATION

There are numerous routes by which shellfish may become contaminated. In many cases, shellfish are impacted before harvest by contamination of the shellfish growing waters by runoff, boat waste discharge, or ineffective sewage treatment plants or septic tanks. At-harvest contamination has also been observed. Two outbreaks of Norwalk virus illness were associated with shellfish contaminated by ill harvesters who vomited overboard during harvesting operations (Kohn et al. 1995, McDonnell et al. 1997). The lack of common sense and training in good sanitation and hygienic practices are major stumbling blocks to enhancing shellfish safety. Postharvest contamination of shellfish and other foods may occur from the unsanitized hands of infected food handlers, contaminated processing surfaces, cross-contamination of the cooked with raw product, or by postharvest adulteration. Shellfish may be adulterated postharvest through the use of unsanitary water, employed either as a food additive or for rinsing product or processing equipment; ice or food additives containing viral contamination; packaging materials; or unsanitary transport or storage conditions. Groups at risk of criminal or civil penalties in the event of a food-borne outbreak include shellfish growers, harvesters, and processors; transporters; retail and wholesale outlets; restaurants; and government regulatory agencies. One prominent outbreak of hepatitis A occurred from the consumption of contaminated oysters from Wallis Lake in New South Wales, Australia (Conaty et al. 2000) and led to a class action suit. The courts found the industry and regulatory agencies liable for millions of dollars in damages because they did not exercise adequate measures to prevent outbreaks of hepatitis A.

STRATEGIES TO REDUCE ENTERIC VIRUSES IN SHELLFISH

Strategies to reduce the incidence of shellfish-related illness must incorporate preharvest, at-harvest, and postharvest interventions (reviewed by Richards, 2001). Some practical approaches directed toward the reduction of preharvest contamination are: (1) improved operation and monitoring of sewage treatment plants that impact coastal areas, (2) elimination of improperly functioning septic tanks from coastal areas, (3) better enforcement of shellfish

harvesting and tagging regulations, (4) enhanced enforcement of ocean-dumping restrictions, and (5) improved shellfish monitoring. Shellfish tagging should be monitored to ensure that shellfish are only obtained from areas approved for harvesting. At-harvest contamination may be reduced by preventing sick shellfishermen from harvesting or handling shellstock. In addition, the discharge of boat wastes, particularly feces, vomitus, and urine, should be strictly forbidden. Postharvest strategies to reduce illness should involve various types of processing to reduce or eliminate potential viral contaminants. Processing may include: (1) thorough washing of shellstock; (2) heating/cooking of shellfish, either in-shell or shucked; (3) irradiation or dehydration of product; and/or (4) depuration and relaying. Thorough cooking is effective in eliminating enteric viruses, but the shellfish may lose many of their desirable characteristics if they are fully cooked. They may become tough, dry, and lose their flavor. In addition, high protein and lipid levels, as are found in shellfish tissues, tend to protect the viruses from thermal inactivation (Filippi & Banwart 1974, Bidawid et al. 2000).

Irradiation can effectively eliminate enteric viruses from shellfish. Ionizing radiation, microwave energy, and ultraviolet irradiation are effective in reducing virus levels. Ionizing radiation was effective in substantially reducing enteric viruses in shellfish, but required a dose that caused rapid shellfish mortalities (Mallett et al. 1991). The use of ionizing radiation may be limited to the disinfection of products destined for shucking. Microwave energy is effective in eliminating shellfish pathogens by virtue of cooking. Uneven heating and the problems associated with marketing a fully cooked shellfish product reduce the feasibility of microwave processing for shellfish. Ultraviolet light can inactivate only surface contaminants, but may be applied in a depuration setting to inactivate pathogens purged from the shellfish during the depuration process. Depuration is the commercial process where shellfish are placed in tanks of clean seawater and allowed to purge contaminants for a short period of time. Ultraviolet light is often used to disinfect the depuration water as it is recirculated through the tank. Over a two- to three-day processing cycle, molluscan shellfish will expel many of the bacteria and viruses, and much of the sediment from their digestive diverticula. Unfortunately, shellfish are unable to purge all the enteric viruses. Some viruses migrate from the digestive diverticula into the epithelial cells surrounding the lumen of the gut and become sequestered within the shellfish tissues (Hay & Scotti 1986, Richards 1990). Since only a few viruses may be sufficient to cause infection, these entrapped viruses limit the effectiveness of depuration in producing a safe product.

Relaying is where shellfish are removed from contaminated shellfish growing areas and placed in clean shellfish growing waters for an extended period (weeks to months) (Richards 1988). Through natural virus inactivation processes, relaying offers some advantages in eliminating viruses that might be sequestered within the shellfish tissues. However, relaying is only effective if the waters remain clean during the entire relay process. This is often difficult to establish since heavy rains, malfunctioning treatment plants, or illegal boat waste discharge could occur at any time during the extended relay period. In addition, shellfish harvesters, pressured to meet customer demands, may be tempted to prematurely harvest shellfish.

Intervention strategies may also include immunizations of food processors and handlers, the general population, children, or just high-risk individuals. There is no consensus on who should be immunized, and the costs and logistics of immunization programs can be daunting. Today, there are vaccines for hepatitis A virus, but the vaccine for rotavirus illness was taken off the market to await further testing. There is no vaccine currently for Norwalk-like viruses; however, vaccines are emerging for hepatitis E virus, which may become a serious public health concern in many countries over the next decade. Immunization programs for food handlers would be extremely difficult to monitor since much of the workforce consists of teenagers who quite frequently move from job to job.

The shellfish industry is increasingly subscribing to the provisions of the hazard analysis critical control point (HACCP) program. The key to HACCP is the delineation of the critical control points in the passage of product from the ocean to the consumer. Under HACCP, the critical control points are monitored to ensure the points are maintained within acceptable limits. Monitoring is practical for some aspects of shellfish sanitation and processing; however, methods to monitor viral contaminants are limited. Consequently, HACCP falls short of protecting the consumer from enteric viruses.

Virus extraction and analytical methods have been developed for a variety of enteric viruses in shellfish. Over the past decade, most of the procedures developed have been based on molecular biological methods, principally reverse transcription-polymerase chain reaction (RT-PCR). Unfortunately, molecular biologically based tests do not differentiate between infectious and inactivated viruses and are only marginally effective in the evaluation of shellfish (Richards 1999). More conventional cell culture-based assays are capable of detecting infectious viruses, but only if the viruses are capable of being propagated in cell or tissue culture. To date, no one has successfully propagated Norwalk-like viruses *in vitro*, and most of the wild-type hepatitis A viruses are incapable of being propagated *in vitro*. Consequently, further research is needed to identify better methods to monitor for the presence of infectious viruses in shellfish.

Overall, there are several measures that can be employed to increase the virological safety of shellfish. The regulation and monitoring of harvesting areas by State and Federal agencies are crucial in providing reasonably clean shellfish in the marketplace. Shellfish must be obtained only from shellfish beds approved for harvesting based on sound sanitary criteria. Proper tagging of raw products will facilitate tracing back to the original source in the event of an outbreak, thus allowing contaminated products to be taken off the market. Efforts to educate shellfish harvesters, processors, and handlers should be enhanced to stress the importance of following the regulations. Thorough cooking is the most effective and simplest method to inactivate enteric viruses in shellfish. If a raw product is desirable, extended relay of moderately or lightly contaminated shellfish into clean water is the most practical procedure to decontaminate large numbers of shellfish. Remediation of shellfish growing waters may be accomplished by continuously monitoring and improving sewage treatment plants and septic systems and by strict enforcement of laws against boat waste discharge. New molecular biological- and cell culture- based assays for the detection of enteric viruses are under development. Future efforts to avert outbreaks of enteric virus illness will likely rely on a combination of enhanced enforcement of existing laws, improved processing and handling techniques, and direct virus testing.

ABSTRACT The paralytic shellfish toxins (PST) are potent neurotoxins. Among them, saxitoxin (STX) is one of the most dangerous for humans and animals, functioning by blocking sodium channels in mammalian nerve cells. Marine algae, such as the dinoflagellate *Alexandrium catenella*, are generally believed to be responsible for the production of STX, and if PSTs are produced by the plankton, they can be concentrated by filter-feeding organisms, effectively increasing the risk of poisoning for consumers of shellfish. However, it is not clear whether *A. catenella* itself, or the bacteria associated with it, produce the toxins and, furthermore, whether toxigenic bacteria are associated, as well, with shellfish contaminated with PST. Bacteria able to produce sodium channel blocking (SCB) toxins were isolated from a toxin-producing *A. catenella* culture and from shellfish (*Aulacomya ater*) contaminated with PST from the Magallanes region of southern Chile. Quantitative levels of PST and bacterial SCB toxins were ascertained by mouse assay and mouse neuroblastoma assay, respectively. More than 60% of the bacteria enriched and analyzed from *Aulacomya ater* and *A. catenella* were observed to produce detectable amounts of SCB. The SCB toxin-producing bacterial isolates were characterized by amplified 16S ribosomal DNA restriction analysis (ARDRA), and selected isolates, representing the different ARDRA groups, were identified by 16S rDNA sequence comparisons and estimations of their phylogenetic relationships with validly published species. Most of the SCB toxin-producing isolates from *A. ater* and from *A. catenella* represent new species of genera within the *Proteobacteria* and, in some cases, demonstrate close phylogenetic relationships with previously reported toxigenic bacteria isolated from other dinoflagellate cultures. However, the isolates from *A. ater* represent different taxonomic lineages from those associated with the dinoflagellate *A. catenella*. These observations suggest that SCB toxin contamination of shellfish may occur independently of algal contamination.

KEY WORDS: toxigenic bacteria, *Alexandrium catenella*, dinoflagellate, shellfish, PSP, saxitoxin

INTRODUCTION

Paralytic shellfish toxins (PST), comprising at least 20 chemically similar derivatives (Oshima et al. 1993) including saxitoxin (STX), are potent neurotoxins that cause paralytic shellfish poisoning (PSP) in humans. PSTs act by blocking sodium channels in mammalian cells, thus preventing conductance of signals along neurons and effectively paralyzing muscle activity (Baden & Trainer 1993). Much evidence has suggested that the PSTs originate from marine dinoflagellates (e.g., of the genera *Alexandrium* and *Gymnodinium*) (Anderson et al. 1990, Cembella 1998). If toxins are present in the plankton, they are concentrated by filter-feeding shellfish and subsequently conveyed to humans via their consumption.

Along the southern Chilean coast, between 1972 and 1998, 348 cases of PSP, including 23 deaths, were reported (Suárez-Isla & Guzmán 1998). The incidences of PSP, in all cases, were associated with the consumption of PST-contaminated mussels. Monitoring also detected the dinoflagellate *Alexandrium catenella* in the PST-contaminated regions, and this species is believed to be responsible for the toxicity in the shellfish (personal communication, Dr. L. Guzmán, Instituto de Fomento Pesquero, IFOP Magallanes, Chile). Sodium channel-blocking (SCB) toxins (i.e., STX) has been detected also in cultures of several species of cyanobacteria: *Aphanizomenon flos-aquae* (Mahmood & Carmichael 1986), *Anabaena circinalis* (Humpage et al. 1994), *Lyngbya wollei* (Carmichael et al. 1997), and *Cylindrospermopsis raciborskii* (Lagos et al. 1999). Further, Negri and Jones (1995) reported high levels of PST in a freshwater mussel when fed with the neurotoxic cyanobacterium *Anabaena circinalis*. Recently, reports have described heterotrophic bacteria as well, isolated from cultures of toxic dinoflagellates, that are capable of producing SCB toxins (Kodama et al. 1988, Doucette & Trick 1995, Franca et al. 1996, Gallacher et al. 1997). These bacteria have been associated with different dinoflagellate species from different geographic regions and represent different taxonomic groups. However, few toxigenic bacteria isolated from shellfish have been described to date (Freitas et al. 1992).

To define further the diversity and potential of toxigenic bacteria associated with PST contamination of shellfish along the southern Chilean coast, isolated bacteria were enriched from mussels (*Aulacomya ater*), collected along the Magallanes coastline of southern Chile, and from a culture of a toxic dinoflagellate (*A. catenella*). The cultivable bacteria from the shellfish and from the dinoflagellate culture were analyzed for SCB toxin production, and the bacterial isolates determined to be toxigenic were characterized systematically.

METHODS

Isolation and Cultivation of Bacteria from PST-Contaminated Mussels (Aulacomya ater) *and from a Toxic Dinoflagellate Culture* (Alexandrium catenella)

Mussels (*Aulacomya ater*) were collected from the Magallanes region of the southern Chilean coast, near Seno Europa (50°03′S, 74°21′W). After collection, the mussels were maintained at 4°C until analysis. The toxicity of the shellfish, as determined by the AOAC mouse bioassay (Williams 1984), was 560 ± 200 μg PST/100 g of mussel flesh (personal communication, Dr. L. Guzman, Instituto de Fomento Pesquero, IFOP Magallanes, Chile). Mussel

tissue was homogenized in NaCl (1%, w/v), using a Tissue Terror. Dilutions of the homogenate were then inoculated into marine broth (Difco Laboratories, Detroit, MI, USA), and 0.1 mL of each dilution was plated onto marine agar medium, prepared with 28‰ sea water. These cultures were incubated at 17°C for at least one week. One hundred colonies with different morphologies were picked and plated individually on marine agar plates, followed by incubation at 17°C for 72 h.

A SCB toxin-producing culture of *Alexandrium catenella*, derived from clone ACC07 from the Aysen region (45°32′S, 73°34′W) in southern Chile, was obtained from Dr. Myriam Sequel (Instituto de Fomento Pesquero, Puerto Montt, Chile). Dilutions of the *A. catenella* culture were prepared, and 0.1 mL were then plated on marine agar medium. These cultures were incubated at 17°C for at least one week. Twenty colonies with observable morphological differences were picked, plated, and incubated as previously described.

Analysis of Toxin Production by Bacterial Isolates

Each bacterial colony was inoculated into 30 mL of marine broth. After incubation at 23–25°C for 36 h on a rotary incubator (100 oscillations per minute), the culture was centrifuged (10,000 × *g*, 20 min), and the supernatants were collected and stored at –20°C until analyzed.

SCB activity in bacterial culture supernatants was measured using a cell-culture assay with mouse neuroblastoma (MNB) (Gallacher & Birkbeck 1992). An STX dose-response curve, using a saxitoxin standard (NRC, Halifax, Canada), was prepared for the range of 0 to 500 nM. All isolate supernatants were tested in triplicate, and controls were done in quadruplicate repeats, as described by Gallacher et al. (1997). The supernatant samples used in the assays were prepared at 1/10 dilutions for all screenings. SCB toxin levels were compared to STX dose-responses to estimate SCB activities with respect to nM STX-equivalents.

Phenotypic and Genotypic Analyses of Toxigenic Bacterial Isolates

Bacterial isolates were characterized by their colony morphology, cultivated on marine agar medium. Staining and microscopic characterization were carried out using standard microbiological methods (Murray & Robinow 1981). API 20 NE strips (BioMerieux Viteck, Inc., Hazelwood, MO, USA) were used as described in API 20 NE protocols for determination of a standard set of phenotypic characteristics. The genotypic diversity of SCB toxin-producing bacteria isolated from the mussel (*A. ater*) tissue samples and from the dinoflagellate (*A. catenella*) culture was investigated using amplified 16S ribosomal DNA restriction analysis (ARDRA) (Vaneechoutter et al. 1992). Bacterial DNA was purified from the isolates as described previously (Espejo et al. 1998). 16S rRNA genes were targeted and amplified by polymerase chain reaction (PCR) using primers and the reaction conditions described by Moore et al. (1996). Subsequently, the amplified 16S rDNA was restricted overnight with 2.5 U of *Hae*III (Gibco BRL, Eggenstein, Germany) or *Msp*I (Gibco BRL) at 37°C or with 5 U *Taq*I (Qiagen GmbH, Hilden, Germany), for three hours at 65°C. The resulting restriction fragments were separated by electrophoresis in 1.5% (w/v) agarose and detected by staining with ethidium bromide (0.5 μg mL^{-1}).

The PCR-16S rDNA was purified using Microcon Centrifugal Filter Devices (Millipore Corp. Bedford, MA, USA) in preparation for nucleic acid sequence determinations and sequenced directly using an Applied Biosystems Inc. 373A DNA Sequencer and the protocol of the manufacturer (Perkin-Elmer, Biosystems, Foster City, CA, USA) for *Taq* cycle-sequencing with fluorescent dye-labeled dideoxynucleotides. The sequencing primers for 16S rRNA have been previously described (Lane 1991).

Analysis of the sequence data and preliminary identifications of the isolates were carried out using the EBI (Baker et al. 2000) interactive Fasta3 search algorithm (Pearson & Lipman 1988).

RESULTS AND DISCUSSION

Nineteen bacterial isolates, picked on the basis of observable morphological differences, were obtained from a culture of an SCB toxin-producing strain of *Alexandrium catenella*. Eleven of these isolates were observed to produce SCB toxin at levels greater than 0.002 fg STX equiv $cell^{-1}$ (Table 1). One of these isolates, MV20, produced amounts of SCB toxins comparable to the level reported by Kodama et al. (1988) for a strain of *Moraxella* sp. All bacteria isolated from the *A. catenella* culture were rod-shaped, Gram-negative, and characterized with the phenotypes listed in Table 2. Five distinct restriction patterns were observed for the 11 toxin-producing isolates, and the 16S rDNAs from two representatives of each ARDRA type were sequenced. The sequence data obtained were compared with reference sequences in the EMBL (Baker et al. 2000), and the approximate identifications of the isolates relative to validly published species are shown in Table 3. As can be expected and was possible to observe, the strains that were closely related, on the basis of their 16S rDNA sequence similarities, also possessed similar phenotypic characteristics (Tables 2, 3). The 16S rDNA sequences determined for the bacteria isolated from the SCB toxin-producing *A. catenella* culture corresponded, in most of the cases, to new species of *Sulfitobacter*, a genus belonging to the α-subclass of the *Proteobacteria* and closely related with the *Roseobacter* phylogenetic lineage (González & Moran 1997). Recently, in separate studies, bacteria of the genus *Roseobacter* or closely related genera have been observed to be associated with toxic dinoflagellates (Lafay et al. 1995, Prokic et al. 1998). *Roseobacter* species appear to be involved in important biogeochemical functions in marine coastal regions, presumably in the cycling of organic and inorganic sulfur (González et al. 1999). These bacteria are able to utilize sulfur compounds provided by phytoplankton, macroalgae, and coastal vascular plants. In that context, it is not surprising to observe species related with the *Roseobacter* group associated with dinoflagellates. Additionally, two isolates, MV05 and MV07, were unrelated with any validly published species and probably represent new species and genera belonging to the γ-subclass of the *Proteobacteria*. The

bacterial diversity in the cultivable community associated with the culture of the SCB toxin-producing *A. catenella* was relatively limited, although a markedly high percentage of the isolates were observed to produce SCB toxins.

One hundred isolates able to grow on marine agar medium were obtained from homogenized tissue of *Aulacomya ater* contaminated with PSP (personal communication, Dr. L. Guzman, IFOP, Magallanes, Chile). *A. ater* is a mussel found typically along the Chilean coast. Eighty of the bacterial isolates were picked for analysis, and a high percentage (77%) was observed to produce SCB in the range between 20 and 100 nM STX equivalents (Table 1). Of the isolates that tested positive for toxin production, 30 with the highest measurable levels of toxin were picked for further analyses. All bacterial isolates from *A. ater* tissue were Gram-negative rods and the phenotypic characteristics for the isolates analyzed (Table 2). On the basis of 16S rDNA sequence comparisons, the 30 isolates were observed to be closely related with species of the genera *Psychrobacter*, of the γ-Proteobacteria subdivision (Table 4). The isolates analyzed were not distinguishable by biochemical testing (Table 2), although 16S rDNA sequence similarities indicated that they comprise at least six distinct clusters, probably corresponding to different species. Although no accepted level of 16S rDNA sequence similarity exists for describing bacterial species, experience has shown that bacteria with 16S rDNA sequence dissimilarities of more than 1% almost certainly comprise different species (unpublished data). Additional phenotypic characteristics must be found to differentiate these bacteria. *Psychrobacter* species and related organisms are found typically in Antarctic sea ice and Antarctic ornithogenic soil (Bowman et al. 1996, 1997). Species of the *Psychrobacter* genus are characteristically psychrophilic or psychrotolerant, as well as halotolerant, with a distribution of species in marine and terrestrial environments. The mussels from which the isolates were obtained were collected in a coastal region with salinity ranging between 22 and

26 gL^{-1} and water temperatures of 6–7°C (depths 0–10 m). It is probably not surprising, at these latitudes, to find psychrophilic or psychrotolerant bacteria associated with the shellfish. Furthermore, the low water temperature may be one reason to have found a lower diversity of cultivable bacteria associated with mussels than what one might expect in more temperate or tropical environments.

This is the first case of SCB toxin production observed in species of *Psychrobacter* and *Sulfitobacter* genera, which suggests that toxin-production in bacteria are not limited to species of *Moraxella*, *Alteromonas*, and *Pseudomonas*, as has been suggested from the results of earlier studies (Doucette & Trick 1995, Kodama et al. 1988). The high percentage of SCB toxin-producing bacteria isolated from the PST-contaminated mussels and from the dinoflagellate culture in this study, as well as results in other previous reports (Gallacher et al. 1997), suggest that this property is not uncommon among marine bacteria. However, SCB toxin is not necessarily related only with saxitoxin, and further analyses (e.g., by other methods such as HPLC and mass spectrometry) need to be included to reliably identify the toxin patterns.

Interestingly, in this study, the range of bacterial diversity obtained from the toxin-contaminated mussels and from the toxic dinoflagellate culture were relatively limited, although past studies using enrichment cultivation methods (Kodama et al. 1988, Doucette & Trick 1995) also recovered only a limited range of bacterial species associated with marine algae. Questions about whether specific species or communities of bacteria are associated with certain algal species or with algal species in defined environmental situations have never been addressed to any degree. Furthermore, the observed high percentage of toxigenic isolates among the cultivable bacteria from the mussels and the dinoflagellate culture raises interesting questions with respect to the influence the associated bacteria may have on production of toxin by the algae and accumulation of toxin by the shellfish. However, the toxin-producing bacteria obtained from the PST-contaminated mussels comprised species from different phylogenetic lineages than those isolated from the toxin-producing dinoflagellate. These observations suggest that the accumulation of PSTs in shellfish may not be dependent only upon the occurrence of toxin-producing marine algae. While it is clear that the shellfish are filtering phytoplankton, including SCB toxin-producing dinoflagellates such as *A. catenella*, the shellfish may have also been obtaining bacteria, the majority of which are found on particulate matter in the marine environment. In the case of our study, the shellfish were collected at a time when monitoring was not detecting significant numbers of *A. catenella* in the water column. However, the shellfish contained high levels of PST. Thus, although the Magallanes region was infected with *A. catenella* blooms at earlier monitoring times, there was no direct influence of marine algae on the toxin levels of the shellfish at the time of our study. It should also be noted that there is usually a lag between the marine algal bloom (in water column) and the detection of PSTs in the shellfish. Results also suggest that toxin-producing bacteria may play a much more important role in PST-contamination of shellfish than has been accepted in the past. Obviously, much more extensive sampling and analysis must be carried out for such a working hypothesis to be tested with any reliability.

ACKNOWLEDGMENTS

We acknowledge Dr. Leonardo Guzman, of the Instituto de Fomento Pesquero (IFOP), Region Magallanes, Chile, for providing the means for sampling and for the analytical information on the toxin levels in mussels; Paulina Uribe, of the Instituto de Ciencias Biomedicas (ICBM), Universidad de Chile, Santiago, Chile, for providing the enrichment from the culture of *Alexandrium catenella* from which the bacterial strains were isolated; Fiona MacKintosh, of the Marine Laboratory, Aberdeen, United Kingdom, for the technical expertise in the analysis of toxin levels in bacterial isolates; and Annette Krüger and Blanca Möller, of the Gesellschaft für Biotechnologische Forschung (GBF), Braunschweig, Germany, for the technical assistance in the nucleic acid fingerprinting and sequencing analyses. The project was supported in part by a grant (1990765) from the Chilean Fondo Nacional de Ciencia y Tecnologia (FONDECYT), an exchange grant (CHL 98/009) from the German Internationales Büro des Bundesministerium für Biotchnologie und Forschung (BMBF) and from the Chilean Comision Nacional de Investigacion en Ciencia y Tecnologia (CONICYT), and a grant (A/3057-1) from the International Foundation for Science (IFS).

PHYTOPLANKTON COMPOSITION AND *PYRODINIUM BAHAMENSE* TOXIC BLOOMS IN MANILA BAY, PHILIPPINES

RHODORA V. AZANZA* AND LILIBETH N. MIRANDA

Marine Science Institute, College of Science, University of the Philippines, Diliman, Quezon City 1101, Philippines

ABSTRACT *Pyrodinium bahamense* var. *compressum* has caused approximately 1,992 paralytic shellfish poisoning (PSP) cases and 116 deaths in the Philippines and has remained the main cause of PSP in the tropical world. The first toxic bloom of the organism in Manila Bay, Philippines was in 1988. Since then the recurrence of the event (usually beginning in April/May and ending in September/October) has been experienced every year except in 1997 and 1999. The latest incident of the phenomenon was in 1998 followed by the absence of the species in 1999 during the months it was present in previous years. Eight stations in Bataan and Cavite, two red tide prone areas in Manila Bay, were sampled during three seasons from 1997 to 1999 for phytoplankton abundance and species composition. Bataan and Cavite, though situated within the same bay, have distinct differences during the three seasons with respect to dinoflagellate population. There is a pronounced increase in dinoflagellate population in Bataan from northeast monsoon to tradewinds to southwest monsoon. In Cavite, dinoflagellates constitute a minor portion of the phytoplankton community during the whole year. In 1998, *Pyrodinium* blooms in both areas started in April/May and terminated in October. A bloom of the heterotrophic dinoflagellate *Noctiluca scintillans* in Bataan and the dominance of the diatom *Chaetoceros* spp. in Cavite succeeded the *Pyrodinium* bloom. *N. scintillans* was observed to be present in the two sites during the entire duration of the study.

KEY WORDS: *Pyrodinium bahamense*, paralytic shellfish poisoning, toxic blooms, Manila Bay

INTRODUCTION

Toxic red tides are recurrent events in the Philippines and have been caused so far only by one dinoflagellate species, *Pyrodinium bahamense* var. *compressum*. Manila Bay is one of the 16 bays affected by this Paralytic Shellfish Poisoning causative organism.

Analysis of the phytoplankton population is an important tool in the proper management of toxic red tides in the country. This helps in the identification of *Pyrodinium* and other potentially harmful algal species that dominate the phytoplankton population during different seasons and the conditions favoring their bloom. Bajarias (1999) has provided an inventory of the dinoflagellates present in 11 marine coastal areas in the Philippines including Manila Bay.

There has been no published work on phytoplankton distribution in Manila Bay. This paper for the first time provides the relative abundance of dinoflagellates and diatom species in two toxic red tide affected areas in the bay for the three different seasons for the period 1997 to 1999.

MATERIALS AND METHODS

Manila Bay is a semi-enclosed bay located at the western coast of Luzon Island, Philippines (lat. 14°53′N; long. 120°76′E) and bounded by the provinces of Cavite in the south, Metro Manila and Rizal in the east, Bulacan and Pampanga in the north, and Bataan in the west and northwest. The bay was first affected in 1988 and annual occurrences of toxic red tides have been recorded (Azanza 1997).

Bataan and Cavite are two areas within Manila Bay that are commonly utilized for shellfish farming and harvest from the wild. Both these areas have a history of red tide occurrences. Phytoplankton monitoring in eight stations in Bataan and Cavite (Fig. 1) was conducted three times for three years covering different seasons (northeast monsoon, tradewinds, and southwest monsoon). Climatological data was obtained from the Philippine Atmospheric, Geophysical and Astronomical Services Administration (PAGASA). Data for Bataan was obtained from Port Area, which is the weather station nearest to the study site.

Samples for phytoplankton analysis were collected using a plankton net with mesh size of 20 μm towed vertically in the water

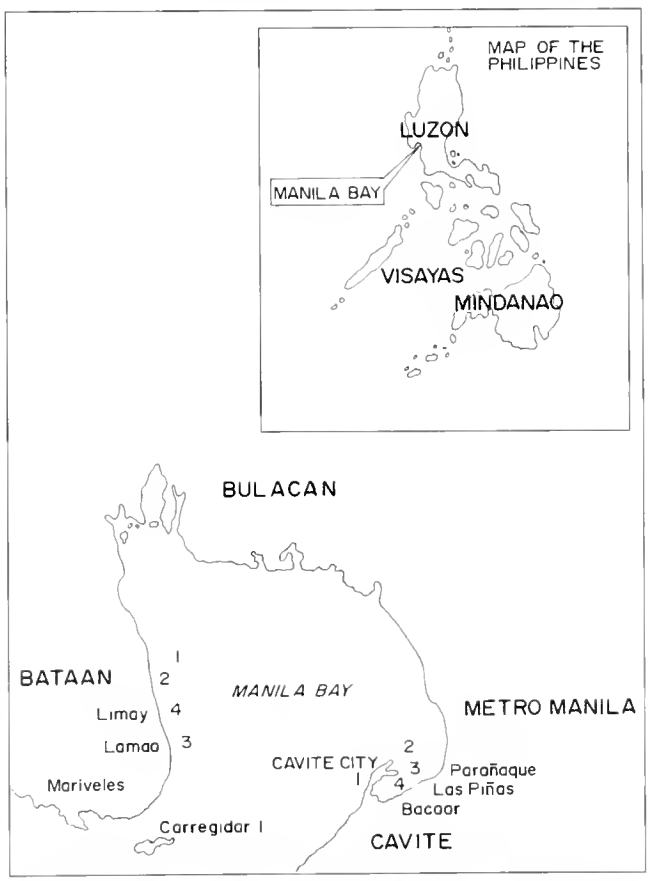

Figure 1. Map of Manila Bay showing the sampling stations in Bataan and Cavite.

*Corresponding author.

column. The cells were preserved by the addition of 1% Lugol's solution. Quantification of plankton was carried out using a Sedgewick Rafter chamber following the technique of Azanza (1997) and Corrales et al. (1995). Identification of phytoplankton was done using the taxonomic keys of Taylor (1976) and Tomas (1997).

RESULTS

Climactic Condition from 1997 to 1999

The climatological conditions during the three years of study are summarized in Figure 2. Cavite had a relatively higher monthly mean air temperature than Bataan. The highest mean air temperature recorded in both places was in the range 34–35°C, occurring during tradewinds in the months of April to May (Fig. 2a). The general rainfall conditions in 1997 and 1998 were relatively similar for the two sites. The amount of rainfall was higher during May to August of 1997, while from 1998 to 1999 there was little variation in the amount of rainfall in both sites (Fig. 2b). The wind force in Cavite ranges from 2–6 mps, while in Bataan it ranges from 2–4 mps (Fig. 2c).

Phytoplankton Composition

The phytoplankton community was composed mainly of diatoms and dinoflagellates. The diatoms were more dominant than dinoflagellates in all samples for the three seasons in the three years of study. There were 10 families of dinoflagellates, nine families of diatoms, and two marine flagellates (raphidophytes and chrysophytes) found in Manila Bay (Table 1). Under dinoflagellates the families *Gonyaulacaceae, Ceratiaceae, Dinophysiaceae, Gymnodiniaceae, Prorocentraceae, Noctilucaceae,*

TABLE 1.

List of phytoplankton species identified in Manila Bay, Philippines.

Family	Species
Dinoflagellates	
Gonyaulacaceae	*Gonyaulax spinifera*
	Alexandrium sp.
	Pyrodinium bahamense var. *compressum*
	Goniodoma sp.
Ceratiaceae	*Ceratium furca*
	Ceratium macroceros
	Ceratium tripos
	Ceratium trichoceros
	Ceratium fusus
	Ceratium breve
	Ceratium carriense
	Ceratium vultur
Dinophysiaceae	*Dinophysis caudata*
	Dinophysis rotundata
	Dinophysis miles
Gymnodiniaceae	*Gyrodinium spirale*
	Gyrodinium sp.
	Gymnodinium catenatum
	Gymnodinium sanguineum
	Cochlodinium sp.
	Polykrikos kofoidii
Prorocentraceae	*Prorocentrum micans*
	Prorocentrum lima
Noctilucaceae	*Noctiluca scintillans*
Peridiniaceae	*Protoperidinium depressum*
	Protoperidinium leonis
	Protoperidinium divergens
	Protoperidinium conicum
	Protoperidinium pellucidum
	Protoperidinium sp.
	Diplopsalis sp.
Pyrocystaceae	*Pyrocystis* sp.
Pyrophacaceae	*Pyrophacus steinii*
Diatoms	
Chaetocerotaceae	*Bacteriastrum* spp.
	Chaetoceros spp.
Coscinodiscaceae	*Coscinodiscus* spp.
Rhizosoleniaceae	*Rhizosolenia* spp.
	Guinardia spp.
Melosiraceae	*Melosira* spp.
Naviculaceae	*Pleurosigma* spp.
	Navicula spp.
Bacillariaceae	*Pseudonitzschia* spp.
Thalassiosiraceae	*Skeletonema* spp.
	Thalassiosira spp.
Thalassionemataceae	*Thalassionema* spp.
	Thalassiothrix spp.
Oscillatoriaceae	*Trichodesmium* spp.
Flagellates	
Chatonellaceae (Raphidophytes)	*Chatonella*
Dictyochaceae (Chrysophytes)	*Dictyocha* spp.

TABLE 2.

Corelation analysis between *Pyrodinium* cell count and climatological conditions.

	Bataan	Cavite
Temperature	0.08389	0.3793
Rainfall	0.2418	0.0203
Wind force	0.0320	−0.0998

Peridiniaceae, *Pyrocystaceae*, and *Pyrophacaceae* were represented. The diatoms belonged to the families *Chaetocerotaceae*, *Coscinodiscaceae*, *Rhizosoleniaceae*, *Melosiraceae*, *Naviculaceae*, *Bacillariaceae*, *Thalassiosiraceae*, *Thalassionemataceae*, and *Oscillatoriaceae*. *Chatonella*, a raphidophyte, and *Dictyocha*, a chrysophyte, were the flagellates present in samples from 1999.

In the majority of the samples, diatoms such as *Skeletonema* spp., *Chaetoceros* spp., *Coscinodiscus* sp., and *Thalassiosira* sp. occurred in high densities. Dinoflagellates such as *Noctiluca scintillans*, *Protoperidinium* spp., and *Ceratium furca* dominated the dinoflagellate population. *Noctiluca scintillans* was consistently present during the three years of study (Fig. 5) with a distinct increase in population during northeast monsoon and tradewinds before the onset of rainy days. *C. furca* formed blooms during the southwest monsoon in 1999 in Bataan waters. *Goniodoma* sp. was present in Bataan waters during April and July 1999. *Noctiluca scintillans* bloomed in Bataan and the diatom *Chaetoceros* spp. in Cavite, both of which succeeded the *Pyrodinium* bloom.

Relative Frequency within Three Seasons

Northeast Monsoon

Diatoms dominated the phytoplankton community in Cavite and Bataan from 1997 to 1999. The dinoflagellates were represented in higher percentage in Bataan (17%) compared to Cavite (7%) (Fig. 3).

Tradewinds

Diatoms dominated this season in Cavite and Bataan with an increase in percentage of dinoflagellates (33%) in Bataan without an increase in Cavite (7%) (Fig. 3).

Southwest Monsoon

Diatoms dominated this season in Cavite, while in Bataan, diatoms (54%) were only slightly more dominant than dinoflagellates (46%) (Fig. 3).

***Pyrodinium bahamense* var. *compressum* Bloom**

Pyrodinium bloomed in 1998 from April to October (Fig. 4). The percentage composition of phytoplankton (Tables 3 and 4) showed that in 1998 *Pyrodinium* dominated the plankton community in Bataan, while in Cavite, the organism also bloomed but not at high enough concentrations to dominate the other phytoplankton species.

Other Potentially Harmful Algal Species

Phytoplankton composition showed the presence of other potentially harmful algal species aside from *Pyrodinium*. These harmful organisms include *Alexandrium* sp., *Gonyaulax* sp., *Gymnodinium catenatum*, *Dinophysis* spp., *Prorocentrum* spp., and *Noctiluca scintillans*. A *N. scintillans* bloom is not toxic but may cause fish kills due to oxygen depletion.

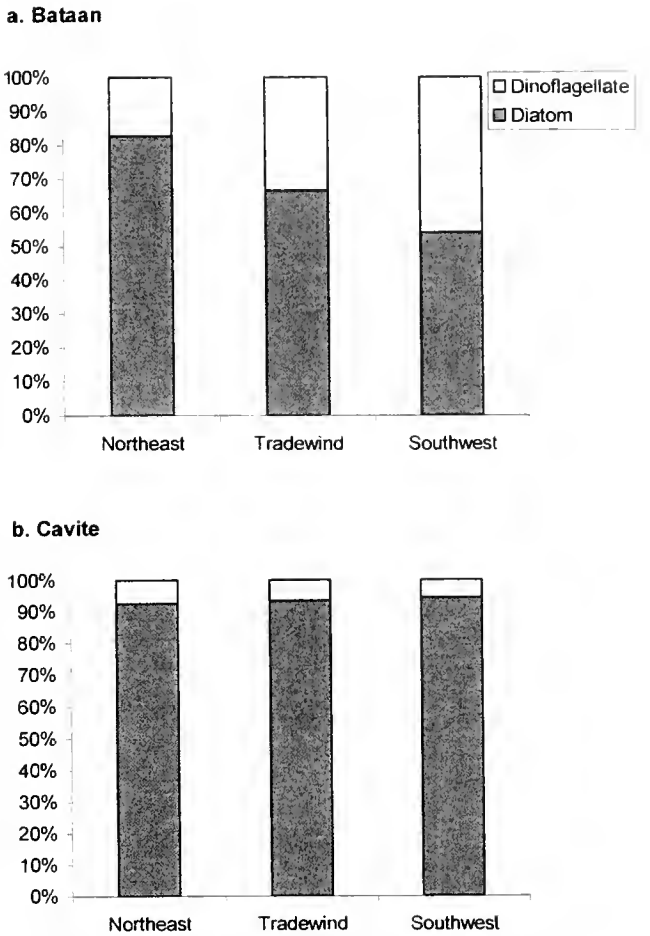

Figure 3. Percentage composition of diatoms and dinoflagellates in 3 different seasons from 1997 to 1999 (a) Bataan and (b) Cavite.

DISCUSSION

Time series data showed that diatoms dominated the phytoplankton population in Manila Bay throughout the three seasons of study (Fig. 3). Bataan and Cavite, though situated within the same bay, have distinct differences during the three seasons with respect to dinoflagellate population. There is a pronounced increase in dinoflagellate population in Bataan from northeast mon-

soon to tradewinds to southwest monsoon, while in Cavite, dinoflagellates constitute a minor portion of the phytoplankton community during the whole year.

No *Pyrodinium* cells were detected in 1997 and 1999. *Pyrodinium bahamense* var. *compressum* bloomed in 1998 during the southwest monsoon, and cells were first detected during the month of April in Bataan and in May in Cavite. *Pyrodinium* red tides in the Bay occurred at the onset of rainy season after a warm dry period similar to the observation of Bajarias and Relox (1996). Peaks of the bloom occurred in months with heavy rainfall (June to August), which was observed in 1991–1994 blooms and also in 1998 *Pyrodinium* bloom. The peak of the bloom occurred during the months of June to August and terminated in October. The 1998 *Pyrodinium* bloom, however, showed a weak relationship with the climatological factors (Fig. 5) based on correlation analysis (Table 2). In terms of rainfall, however, *Pyrodinium* bloom started at the onset of the rainy season just after a dry period (Figs. 5b, 5c), which is necessary in the initiation of *Pyrodinium* blooms as discussed by Corrales and Crisostomo (1996), Bajarias and Relox (1996), Velasquez et al. (1997), and Azanza et al. (1998).

Previous studies by Corrales and Hall (1993), Bajarias and Relox (1996), and Velasquez et al. (1997) showed the optimal environmental conditions (i.e., water temperature, salinity, rainfall, and nutrients) for the growth of *Pyrodinium* culture in the laboratory and in the field. The amount and availability of dissolved nutrients in the water column play a significant role in regulating the bloom of *Pyrodinium* (Velasquez et al. 1997).

Villanoy et al. (1996) studied the distribution patterns of *Pyrodinium* cyst density, which indicates that the onset of the algal bloom may be related to some physical, chemical, and biological factors in the bay. Manila Bay water circulation is described to have a double-gyre system where one gyre is located at the western side (Bataan) and the other is at the eastern side (Cavite) (Yniquez et al., 2000). The nonoccurrence of the *Pyrodinium* bloom in 1997 and 1999 needs to be studied further through ecophysiological experiments and field studies.

ACKNOWLEDGMENTS

Funding support from International Atomic Energy Agency and the Philippine Council for Aquatic and Marine Research and Development is gratefully acknowledged. Help in the field work, statistical analysis, and poster preparation was provided by Lita dela Cruz, Aletta Yñiquez, and Arlynn Gedaria, respectively. The Organizing Committee provided assistance for the senior author's attendance of the 3rd ICMSS.

DISTRIBUTION OF *GYMNODINIUM CATENATUM* GRAHAM AND SHELLFISH TOXICITY ON THE COAST OF SUCRE STATE, VENEZUELA, FROM 1989 TO 1998

AMELIA LA BARBARA-SANCHEZ* AND JESUS F. GAMBOA-MARUEZ
INIA-CIAE Sucre/Nueva Esparta, P. O. Box 236, Cumaná, estado Sucre, 6101, Venezuela

ABSTRACT *Gymnodinium catenatum* blooms were first detected on the Venezuelan coasts in 1989. Since then, monitoring along the northeastern coast of Sucre state and the Gulf of Cariaco was carried out to detect the presence of this organism and to measure environmental parameters (temperature and salinity) that may be associated with its appearance. *G. catenatum* has been observed every year along the coast, with maximum abundance between June and October. Blooms of *G. catenatum* (> 1,000 cells · ml^{-1}) have been recorded only in the northeastern coast during the rainy season (July – Nov.) when water temperature was above 25°C and salinity was 36.5 to 38‰. The lowest abundance (< 100 cells · ml^{-1}) occurred from Dec. – June in a wide range of temperature (22–28°C) and salinity (33.2–39 ‰). The species has been less abundant in the Gulf of Cariaco and has not formed blooms yet. The dynamics of the marine environment at the north coast seem to favor the growth of *G. catenatum* populations. Shellfish toxicity showed different PSP levels and did not always coincide with the presence of *G. catenatum*.

KEY WORDS: *Gymnodinium catenatum*, shellfish toxicity, Sucre state, Venezuela

INTRODUCTION

Algal blooms in the coastal waters of northeastern Venezuela occur with yearly frequency. Many blooms are associated with toxigenic species that induce toxicity in bivalve mollusks, which can have severe impacts on public health, on the regional economy, and upon the marine environment. Ferraz-Reyes (1992) reported that red tide events off the northeastern coast of Venezuela occur mainly during the dry season and occasionally during the rainy season.

One of the species responsible for blooms along the coast of Sucre state has been *Gymnodinium catenatum* (Graham 1943). Its appearance has been associated with PSP toxicity of bivalve mollusks of commercial value (La Barbera-Sánchez et al. 1993). The species was first detected in Venezuelan waters in 1989. Since then it has reappeared several times, causing PSP on the northeastern coast of Sucre state. This athecate dinoflagellate has a widespread distribution. It has been reported from the Mexican Pacific Coast (Morey-Gaines 1982, Mee et al. 1986), the coasts of Argentina (Balech 1964), the Atlantic Coast of Spain (Estrada et al. 1984, Fraga et al. 1988), the Mediterranean Coast (Carrada et al. 1991), and Australia (Oshima et al. 1987, Hallegraeff et al. 1989).

The presence of *G. catenatum* in Venezuelan coastal waters is associated with certain environmental conditions, particularly with intrusion of warm seawater and periods of upwelling relaxation. Fraga et al. (1988, 1990) and Fraga (1996) associated the presence of *G. catenatum* with the introduction of surface warm waters from offshore toward coastal inlets during the period of upwelling relaxation after summer time. In this study, the presence and abundance of *G. catenatum* is compared with observed trends of salinity and temperature of coastal waters in Sucre state, and toxicity events during the monitoring program performed from 1989 to 1998.

MATERIALS AND METHODS

A monitoring program to detect the presence of toxic algae in the plankton and toxicity episodes in bivalve mollusks was implemented from 1989 to 1998. Water samples were taken at sea surface and 3 m deep every 15 days, in different localities along the coast of Sucre state where bivalve mollusks beds are found. Three sampling sectors were established: the northeastern sector with stations at Bahía Patilla, La Iglesia, and San Juan de Las Galdonas; the northwestern sector with two stations at Chacopata; and the southwestern sector with stations at La Chica and Peñas Blancas within the Gulf of Cariaco (Fig. 1).

Water samples were obtained using a Van Dorn bottle, with a portion fixed with Lugol solution for quantitative cell counts by the Utermöhl (1958) method. The other portion was used to measure water temperature with a thermometer (A = 1°C) and salinity with an ATAGO refractometer (A = 0.1‰). Transparency at each sampling station was measured using a Secchi disc. Phytoplankton samples were also obtained using a net with 25 μm mesh for species identification.

The concentrations of PSP toxins in ark shells (*Arca zebra*) and mussels (*Perna perna*) were measured by mouse bioassay (AOAC 1984).

RESULTS AND DISCUSSION

Gymnodinium catenatum has a wide distribution on the coast of Sucre state. The species was first found in the coastal zone of Sucre state within waters of the Gulf of Cariaco during 1986, in very low density. In April-May 1988, *G. catenatum* appeared in coexistence with *Alexandrium tamarense*, *Gonyaulax* cf. *sousa*, and *Gonyaulax polygramma*, in a bloom caused by the latter species, which caused toxicity in the mussel, *Perna perna*, cultivated in the Gulf of Cariaco (La Barbera-Sánchez et al. 1993).

In 1989, blooms of *G. catenatum* were recorded in the northeastern and northwestern sectors of Sucre state, with abundance larger than 10×10^2 cells · ml^{-1} in February and April (Fig. 2). *G. catenatum* coexisted in low abundance with *A. tamarense* and *A. monilatum*. The presence of *G. catenatum* in these sectors was associated with toxicity events of PSP, which reached levels higher than 600 μg STX/100 g meat and affected several species of bivalve mollusks of commercial value (La Barbera-Sánchez *op*

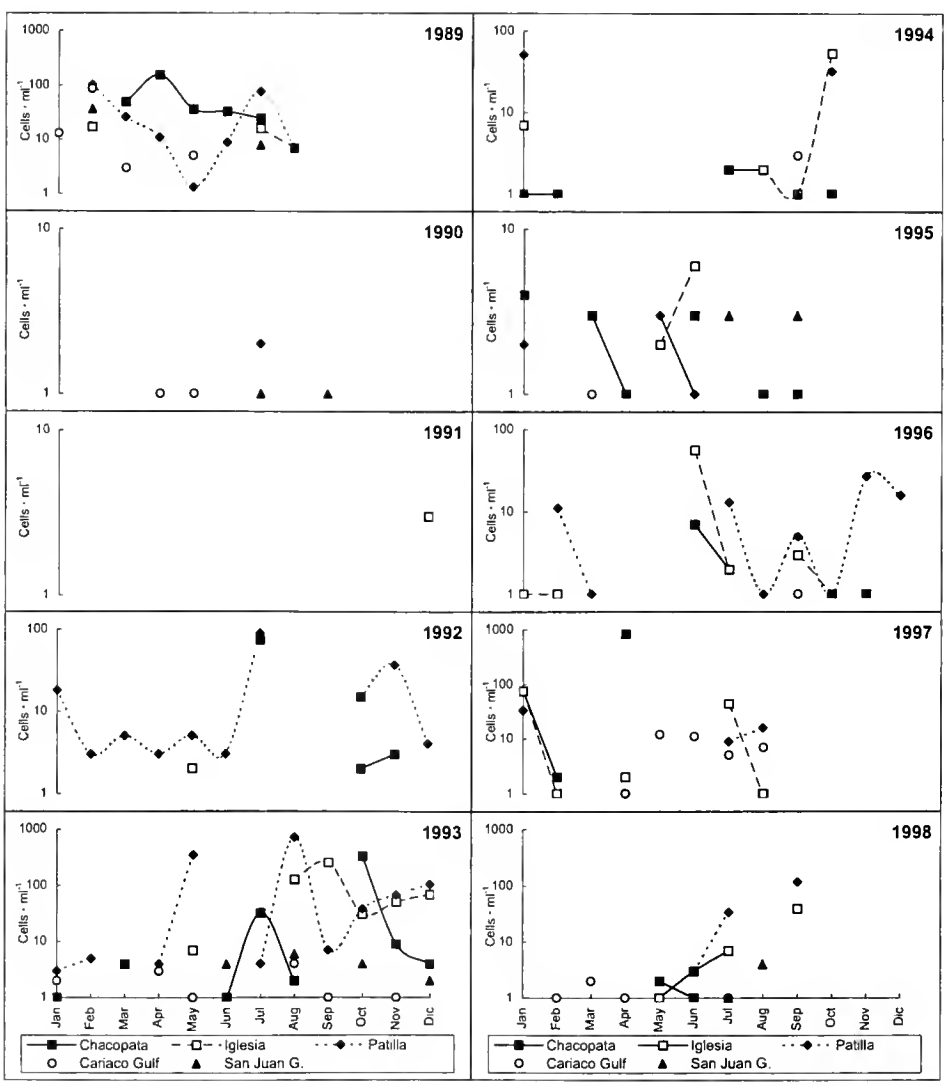

Figure 2. Abundance variation of *Gymnodinium catenatum* on the coast of Sucre state, Venezuela: 1989–1998.

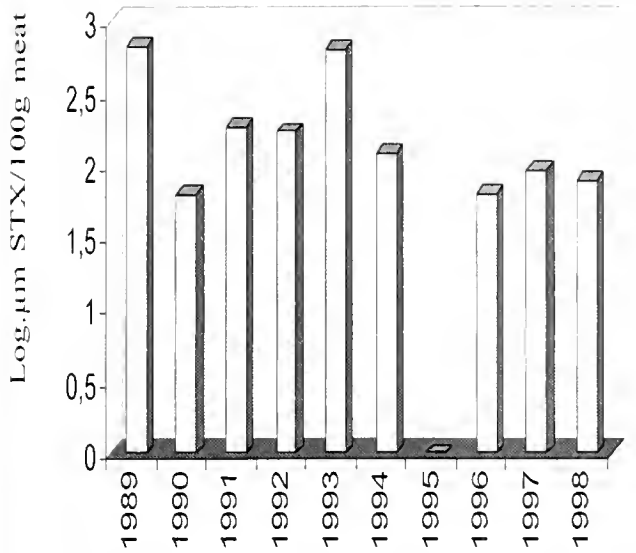

Figure 3. Variation annual mean of the toxin concentration on the coast of Sucre state.

cit.). In the northeastern sector, toxicity levels in the mussel, *P. perna*, and the clam, *Tivela mactroides*, reached values higher than 1,000 µg STX/100 g meat. The death of mussels in natural banks was also observed. In the northwestern sector, the levels of PSP toxin in ark shells, *Arca zebra*, were beyond those permitted for human consumption. These events caused intoxication by consumption of bivalve mollusks in 15 persons, and great economic impact in the region.

During the period 1990–92, *G. catenatum* was observed in low abundance (Fig. 2), but the number of observed organisms (from < 1 to 10^2) in the northeastern sector did not correspond with toxicity levels recorded in the mussel, *P. perna*, during 1991 and 1992 (Fig. 3).

In 1993, *G. catenatum* was observed during the entire year in the northeastern sector with variable densities (from 1 to 1,342 cells · ml^{-1}). The highest abundance was recorded in May, August, September, and October, while the lowest abundance was observed during the first months of the year (Fig. 2). The period of highest densities coincided with episodes of toxicity in November and December (1,255 µg STX/100g meat) that extended until October 1994, at toxicity levels of 100 µg STX/100g meat.

In 1994, *G. catenatum* registered low abundance and there was toxicity in mussels almost all year long, with maximum levels between January and April. However, there was no correspondence between the toxicity levels and the scarcity of vegetative cells of the toxic species. January and April are months of strong upwelling along the coasts off Sucre state; therefore, it is possible that the toxic event may have been originated by cysts resuspended by upwelling in the water column, as has also been pointed out by La Barbera-Sánchez and Estrella (1996).

The years 1995, 1996, 1997, and 1998 (Fig. 2) were notorious for the low number of cells of *G. catenatum*, except in the northwestern sector, where there were increases in April 1997 (984 cells · ml^{-1}) at surface level. Otherwise, the levels of toxicity for PSP stayed low, with a total absence in 1995.

For the years 1989 and 1993 the toxicity levels in bivalve mollusks of Sucre coasts were higher than the allowable maximums (> 600 µg STX/100 g meat) (Fig. 3). The toxic levels for 1990, 1996, and 1998 were lower than 80 µg STX/100 g meat. The levels for the remaining years in the study yielded values between 90 and 190 µg STX/100 g meat.

G. catenatum was always present in the area, at varying temperatures and salinities. It appears in higher density from July to February in coincidence with the rainy season (from June to November) and with the onset of trade winds and upwelling (November, December, January, and February) (Figs. 4 a, b, c).

G. catenatum recorded low densities within a wide range of temperatures (22–28°C) and salinity gradients (33.2 –39‰). Blooms of the organism (> 1,000 cells · ml^{-1}) were observed in 1989 (February), 1993 (May, August, September, and October), 1997 (January, April), and 1998 (September), in waters with temperatures above 24°C and salinity gradients between 35.5 and 38‰ during the rainy season, contrasting with the southwestern sector (Gulf of Cariaco), where the species has not bloomed yet (Fig. 4 a). The species was more abundant and frequent in the northwestern and northeastern sectors (Figs. 4 b and c). However, this behavior is more evident in the northeastern sector (Fig. 4 c), where the species has a spatial and seasonal distribution.

The northeastern sector is characterized by strong swelling and by the influence of the low salinity and influx of nutrients from the Gulf of Paria and adjacent regions (Okuda et al. 1974). It has, in addition, increased orthophosphate content during the rainy season, which favors blooms of diatoms and dinoflagellates (La Barbera-Sánchez et al. 1988). Figueiras and Pazos (1991) reported dense overgrowths of *G. catenatum* in water bodies of intense agitation, similar to what this study found for the northeastern region. Thus, the increase in the number of cells may be influenced by soil and wastes washed off by rain. This phenomenon affects the saline concentrations and incorporates organic and inorganic elements that serve as nutrient sources for the species. Peperzak et al. (1996) reported that an increase of freshwater in coastal areas may result in a transient stratification of salinity and reduced turbulence. This allows for greater stability of the water column and favors the growth of dinoflagellates. However, it has been found that it is thermal stratification, rather than salinity stratification, that leads to dinoflagellate accumulation and dominance. Likewise, La Barbera-Sánchez and Estrella (1996) found a significant correlation between proliferation of *G. catenatum* during the rainy season with temperature and transparency in the northeastern sector of the coast of Sucre.

Results have revealed that the distribution of *G. catenatum* along the coast of Sucre state does not seem to be related to the temperature and salinity. However, the abundance and the periods of toxicity do point to a transient relationship with temperature increases and rainy seasons. The dynamics of the marine environment along the northwestern and northeastern sectors in the coast of Sucre state, which need to be fully studied, seem to favor the growth of *G. catenatum* populations, perhaps due to a greater availability of nutrients or to the presence of some oligoelement in the water during the rainy season.

PIGMENT PROFILE AND VIOLAXANTHIN CYCLE OF *HETEROSIGMA AKASHIWO* (RAPHIDOPHYCEAE)

YUTAKA OKUMURA,[1]* MAKOTO YAMASAKI,[2] TOSHIYUKI SUZUKI,[1] KAZUHIKO ICHIMI,[3] AND OSAMU OKU[3]

[1]*Tohoku National Fisheries Research Institute, 3-27-5 Shinhama, Shiogama, Miyagi 985-0001, Japan;* [2]*National Research Institute of Aquaculture, 422-1 Nakatsuhamaura, Nansei, Watarai, Mie 516-0193, Japan;* [3]*Japan Science and Technology Corporation 4-1-8 Honchou, Kawaguchi, Saitama 332-0012, Japan*

ABSTRACT Pigment profiles of the Raphidophycean *Heterosigma akashiwo* were analyzed by high-performance liquid chromatography (HPLC) with a diode array detector. Chlorophyll $c_1 + c_2$, fucoxanthin, violaxanthin, antheraxanthin, zeaxanthin, chlorophyll *a*, and β-carotene in three strains of *H. akashiwo* (NIES6, 10, 293) were identified. The pigment profiles of *H. akashiwo* in a light:dark cycle were also analyzed by HPLC. The peaks of antheraxanthin and zeaxanthin were higher in the light, while the reverse was recorded for violaxanthin. This is the first evidence of the existence of a violaxanthin cycle in Raphidophyceae.

KEY WORDS: Raphidophyceae, *Heterosigma akashiwo*, pigments

INTRODUCTION

Since the analysis of microalgal pigments by high-performance liquid chromatography (HPLC) was developed (Mantoura and Llewellyn 1983, Wright and Shearer 1984, Wright et al. 1991, Suzuki et al. 1993, Latasa et al. 1996, Furuya et al. 1998), the pigment profiles of many classes of microalgae have been analyzed by this method (Kohata et al. 1991, Suzuki and Ishimaru 1992, Garrido and Zapata 1998). In particular, HPLC analysis of pigments has been conducted to investigate marine microalgal species that contribute to primary production (Gieskes and Kraay 1983, 1986, Goericke and Repeta 1993, Letelier et al. 1993, Andersen et al. 1996, Bidigare and Ondrusek 1996, Roy et al. 1996, Suzuki et al. 1997). Analysis by HPLC is also useful to study the synthesis of microalgal pigments, such as in the diadinoxanthin cycle and violaxanthin cycle (Goericke and Welschmeyer 1992, Porra et al. 1997, Lohr and Wilhelm 1998, Oku and Kamatani 1999). In recent years, several reports (Fiksdahl et al. 1984a, Fiksdahl et al. 1984b, Yamaoka and Takimura 1985, Kohata and Watanabe 1988, Kohata et al. 1991) and a review (Jeffrey and Vesk 1997) of pigment profiles of harmful algae of the family Raphidophyceae have been published. It is interesting that these profiles, in particular that of *Heterosigma akashiwo*, differ among the reports (Fiksdahl et al. 1984b, Yamaoka and Takimura, 1985, Kohata et al. 1991), suggesting variation in the pigment profiles of such species.

In the present study, detailed pigment profiles of three strains of *H. akashiwo* were obtained and the violaxanthin cycle of this species was investigated.

MATERIALS AND METHODS

Pigment Analysis by HPLC

The following marine microalgae with known major pigments were cultured: Rhodophyceae, *Porphyridium cruentum* (CSIRO25); Bacillariophyceae, *Phaeodactylum tricornutum* (CSIRO29); Chlorophyceae, *Dunaliella tertiolecta* (CSIRO175); and Dinophyceae, *Amphidinium cartererae* (CSIRO212), all obtained from the CSIRO Microalgae Research Centre, CSIRO Marine Research Laboratories, Tasmania. Culture conditions were: temperature 21 ± 1°C, illumination 8000 ± 1000 lux and a light: dark cycle of 14:10 hours. Test tubes (25 × 200 mm, 64 ml) containing 30 ml of f/2 medium (Guillard and Ryther 1962) were used as the culture vessels.

Thirty milliliters of the growth phase medium were filtered on glass-fiber filters (Whatman GF/F). The filters were then extracted with 10 ml *N, N* -dimethylformamide (DMF) (Suzuki and Ishimaru, 1990). Chlorophyll *a* standard (Chl *a*; Wako Pure Chemicals, Ltd.) was also dissolved in DMF. Each algal sample extract and the Chl *a* standard were chromatographed on an STR ODSII column (Shimadzu Chemical Industries, Ltd.) with a Shimadzu Raphidophyceae HPLC system (system controller, SCL-10AVP; auto injector, SIL-10ADVP; liquid chromatograph, LC-10ATVP; column oven, CTO-10AVP; and diode array detector, SPD-M10AVP). The temperature of the column was kept at 40°C. The HPLC solvent system followed the modified method of Suzuki et al. (1997) as shown in Table 1.

After pigment separation by HPLC, individual pigments were identified from published data of their diode array spectra (Jeffrey et al. 1997).

Analysis of Pigment Distribution in Three Strains of H. akashiwo

Three strains of *H. akashiwo* (NIES6, NIES10, NIES293) obtained from the Microbial Culture Collection, National Institute for

Environmental Studies (NIES Collection), Environment Agency, Japan, were cultured and pigments analyzed using procedures as mentioned above. Identification of the pigments was made by comparison of their retention time with standard and diode array spectra of pigments of the other cultured microalgae.

Response of Pigments of H. akashiwo to a Light:Dark Cycle (Light Intensity)

H. akashiwo NIES6 was pre-cultured in three test tubes with 30 ml of f/2 medium. 30 ml of medium from the exponential growth phase was added to three 300 ml glass Erlenmeyer flasks containing 200 ml of f/2 medium. The microalgae were cultured under illumination of 8000±1000 lux with a light:dark cycle of 14:10 hours for four days.

The microalgae were harvested in their growth phase after 11 and 13 hours of light period (L11 h, L13 h), 10 hours of dark period (D10 h), 4 and 11 hours in the next light period (NL 4 h and NL 11 h) and 8 hours in the next dark period (ND 8 h).

The samples were frozen at −80°C immediately after filtering the cultures using glass-fiber filters. After the samples were harvested, they were extracted in DMF for 24 hours and analyzed by HPLC.

RESULTS AND DISCUSSION

Pigment Analysis by HPLC

The absorbance maxima (nm) of the pigments (Table 2) were close to those reported by Jeffrey et al. (1997). This also indicates that there was no significant influence of variations in the extraction solvent and HPLC mobile phase on the spectra of the pigments.

Analysis of Pigment Profiles in the Three Strains of H. akashiwo

The major pigments of the three strains of *H. akashiwo* (NIES6, 10, 293) were eluted from the column in the order: chl c_1 + c_2, fucoxanthin, violaxanthin, antheraxanthin, zeaxanthin, chl *a*, and β-carotene (Fig.1). The major pigments of Raphidophyceae, in particularly *H. akashiwo*, have varied among the published reports. Jeffrey and Vesk (1997) reported that the major pigments in Raphidophyceae are fucoxanthin, violaxanthin, and β,β-carotene, while Fiksdahl et al. (1984a) mentioned that the major pigments of

Extraction in 90% acetone

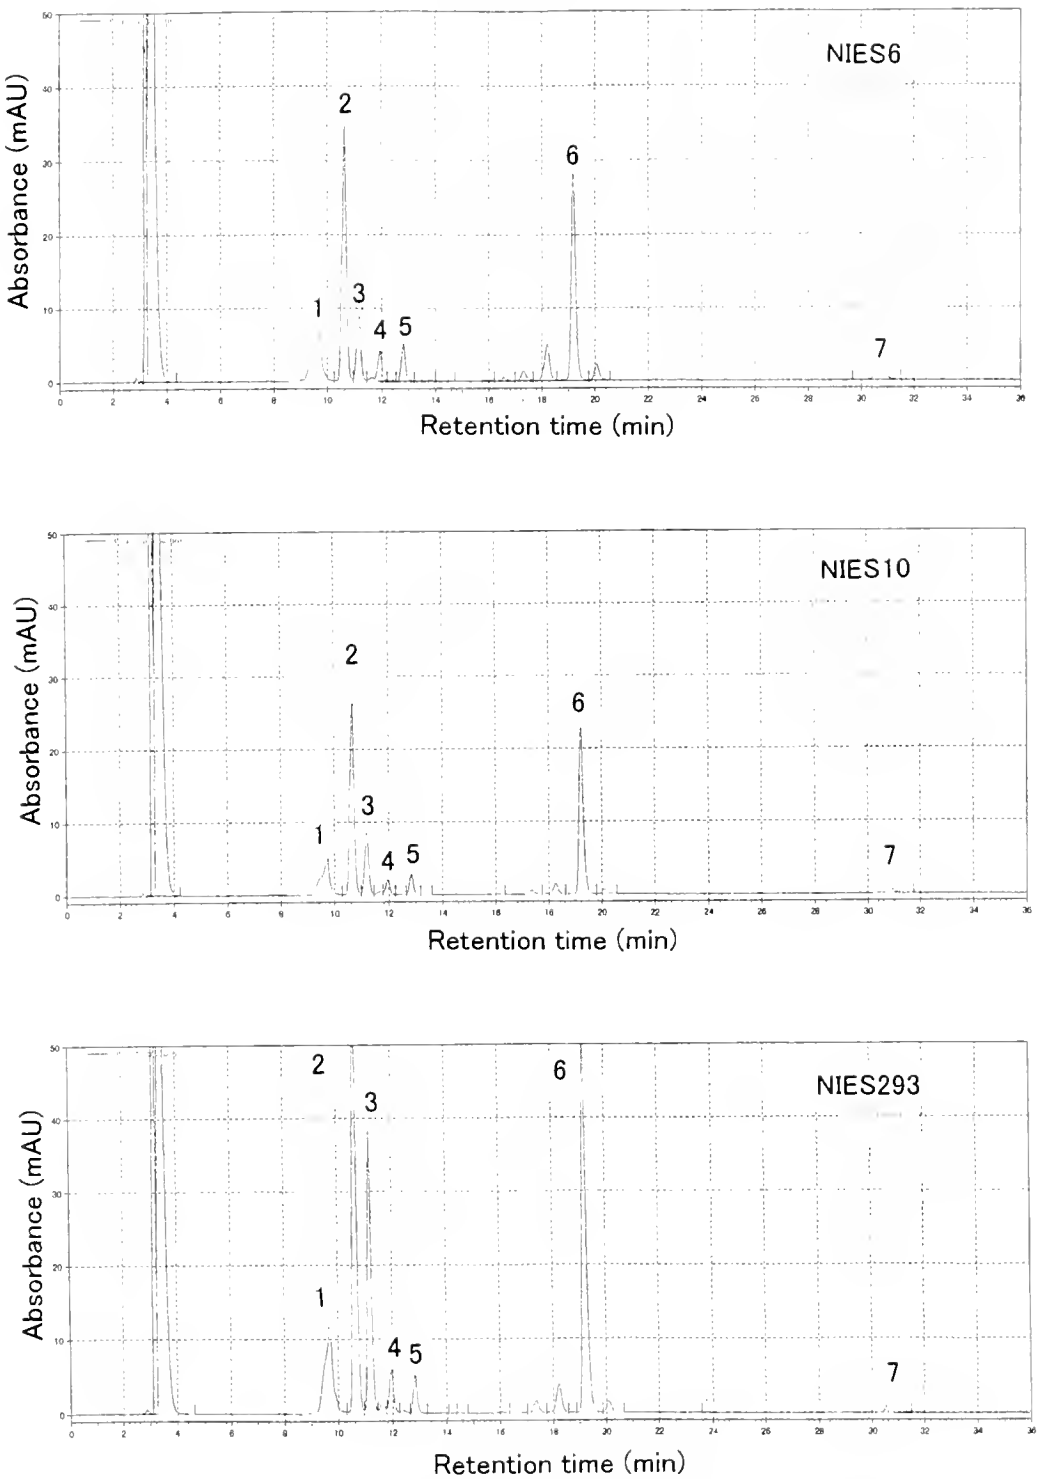

Figure 1. Typical chromatograms (435 nm) of three strains of *H. akashiwo* (NIES6, 10, 293). Individual peaks are (1) Chl c_1+c_2, (2) fucoxanthin, (3) violaxanthin, (4) antheraxanthin, (5) zeaxanthin, (6) Chl *a*, and (7) β-carotene.

Raphidophyceae are chl *a*, c_1 + c_2, fucoxanthin, violaxanthin, zeaxanthin, and β-carotene. Fiksdahl et al. (1984b) also reported that the major carotenoid in *H. akashiwo* is peridinin; fucoxanthin was not observed in their study. Yamaoka and Takimura (1985) observed that in *H. akashiwo*, fucoxanthin and β-carotene are present as major pigments while zeaxanthin was absent. Carotenoids of *C. antiqua* were fucoxanthin, violaxanthin, and β-carotene in Kohata and Watanabe's work (1988). Kohata et al. (1991) reported that fucoxanthin, violaxanthin, antheraxanthin, zeaxanthin, and β-carotene were the major carotenoids of *H. akashiwo*. The pigment

profile of *H. akashiwo* in the present experiment was similar to that reported by Kohata et al. (1991).

Response of Pigments of H. akashiwo to a Light:Dark Cycle (Light Intensity)

The peaks of antheraxanthin and zeaxanthin (L11 h, L13 h, NL4 h and NL11 h) in the light were higher than those obtained under conditions of darkness (D10 h and ND8 h) (Fig.2). The reverse, however, was the case for violaxanthin. It is known that pigment profiles in Bacillariophyceae and Dinophyceae vary with light intensity. There is the so-called "diadinoxanthin cycle" in which diatoxanthin is epoxidized to diadinoxanthin in darkness and de-epoxidized from diadinoxanthin to diatoxanthin in the light (Goericke and Welschmeyer 1992, Lohr and Wilhelm 1998). The "violaxanthin cycle" is another reported cycle relating to photo-

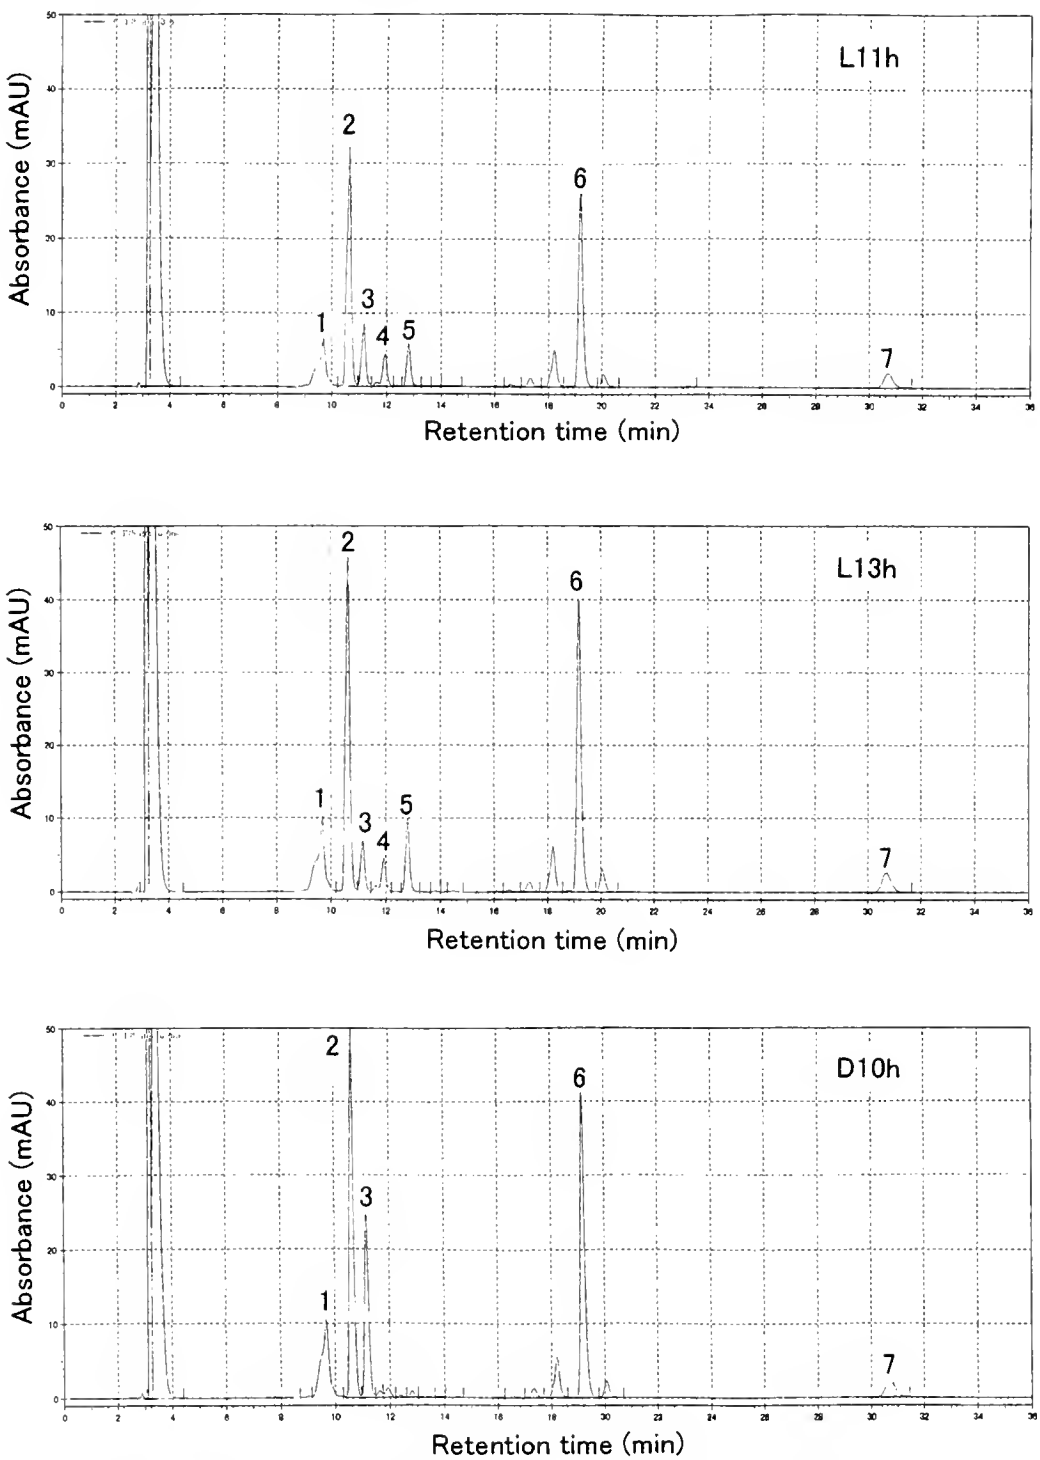

Figure 2. Typical chromatograms (435 nm) of *H. akashiwo* (NIES6) under a light:dark cycle. Individual peaks are (1) Chl $c_1 + c_2$, (2) fucoxanthin, (3) violaxanthin, (4) antheraxanthin, (5) zeaxanthin, (6) Chl *a*, and (7) β-carotene.

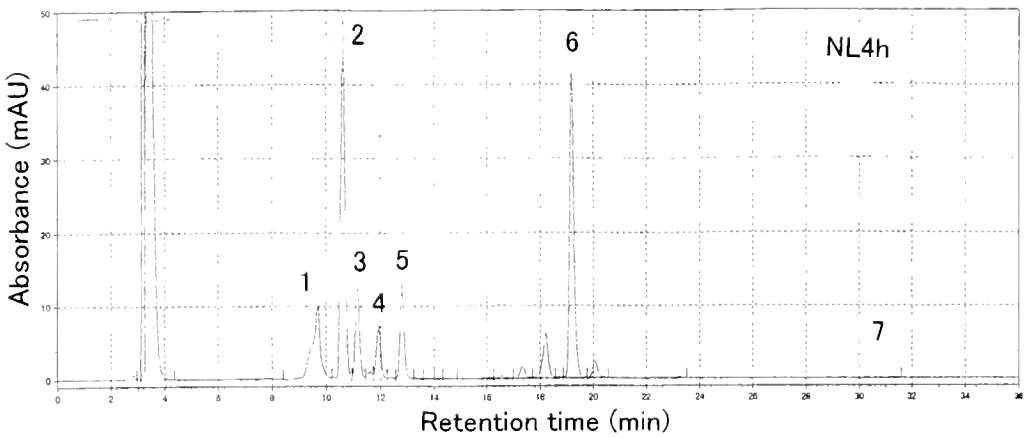

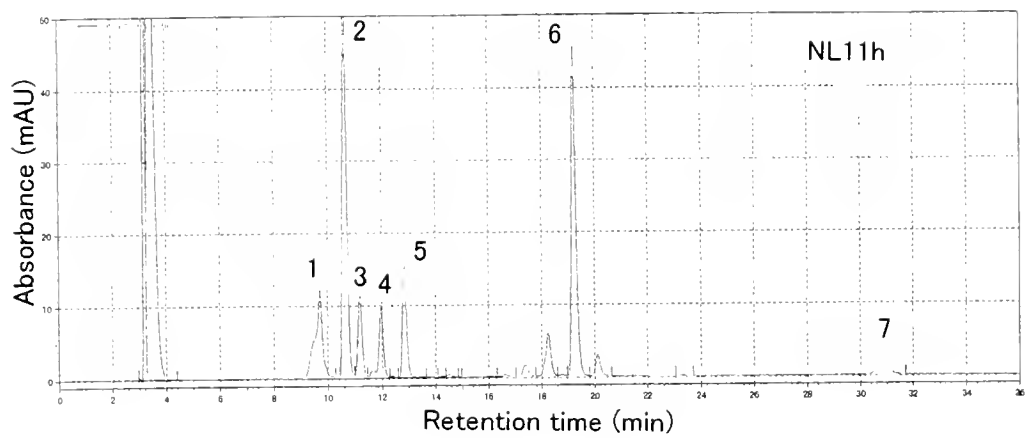

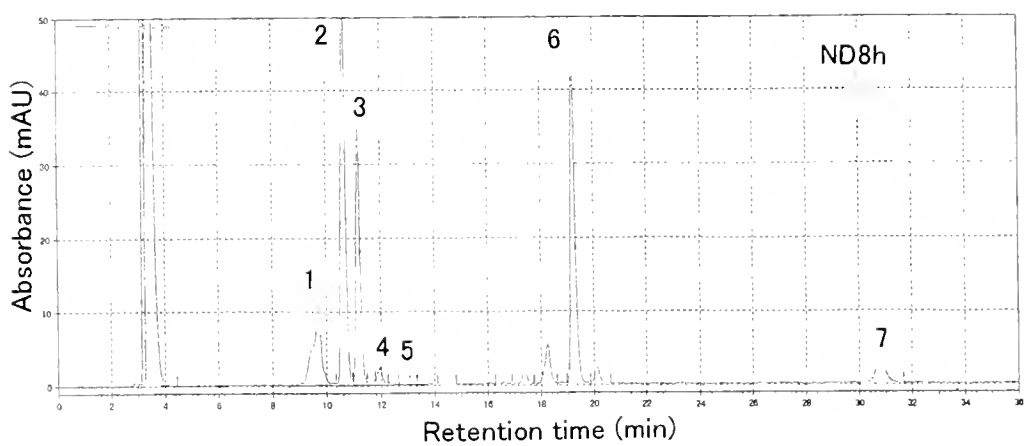

Figure 2. Continued.

chemical epoxidation : zeaxanthin and antheraxanthin are epoxidized to antheraxanthin and violaxanthin, respectively, in the dark, and these epoxidized materials are de-epoxidized to the original materials in the light (Porra et al. 1997, Lohr and Wilhelm 1999). Although diadinoxanthin and violaxanthin cycles have been observed in Bacillariophyceae, Xanthophyceae, Haptophyceae, and Dinophyceae (e.g., Willemoes and Monas 1991, Arsalane et al. 1994, Oku and Kamatani 1999, Lohr and Wilhelm 1999), the violaxanthin cycle in *H.akashiwo* has not previously been reported. Our observation is the first evidence of the existence of the violaxanthin cycle in Raphidophyceae.

ABSTRACT In the last decade, the bloom-forming dinoflagellate *Heterocapsa circularisquama* Horiguchi has caused red tides along the Japanese coast. Because this dinoflagellate shows a detrimental effect on molluscan shellfishes such as bivalves and gastropods, almost all red tides have associated catastrophic death of farmed animals. Recent proliferations of *H. circularisquama* throughout the western Japanese coast have devastated the shellfish aquaculture industries and are a cause for concern due to the consequent economic losses.

KEY WORDS: *Heterocapsa circularisquama*, red tide, shellfish, death, toxicity

INTRODUCTION

Current proliferation of harmful algal blooms causes serious problems for public health and fisheries industries (Okaichi 1989, Smayda 1990, Shumway 1990, Hallegraeff 1993, Anderson 1994, Honjo 1994). On the Japanese coast, the novel marine dinoflagellate *Heterocapsa circularisquama* Horiguchi (Horiguchi 1995), appeared in 1988 and then rapidly expanded over the western area (Matsuyama et al. 1996). Red tides due to *H. circularisquama* have damaged shellfish aquaculture in most of the region (Yamamoto & Tanaka 1990, Yoshida & Miyamoto 1995, Matsuyama et al. 1996, Etou et al. 1998). Although *H. circularisquama* blooms mainly affect shellfisheries aquaculture, no harmful effects on wild and cultured finfish, other marine vertebrates, and public health hazards were recorded. Incidence of blooms of this species has increased recently, and the economic losses in aquaculture have been a cause for concern for the shellfisheries industry and society (Matsuyama et al. 1996). In the present article, we review the damage caused to aquaculture and the toxicity of the organism.

DAMAGE TO SHELLFISHERIES AND TOXICITY

Red Tide and Shellfish Damage in Aquaculture Industries

The first incidence of red tide due to *H. circularisquama* and subsequent death of shellfish occurred in Uranouchi Bay, on the southern part of Shikoku Island (Fig. 1) in 1988. Red tide due to

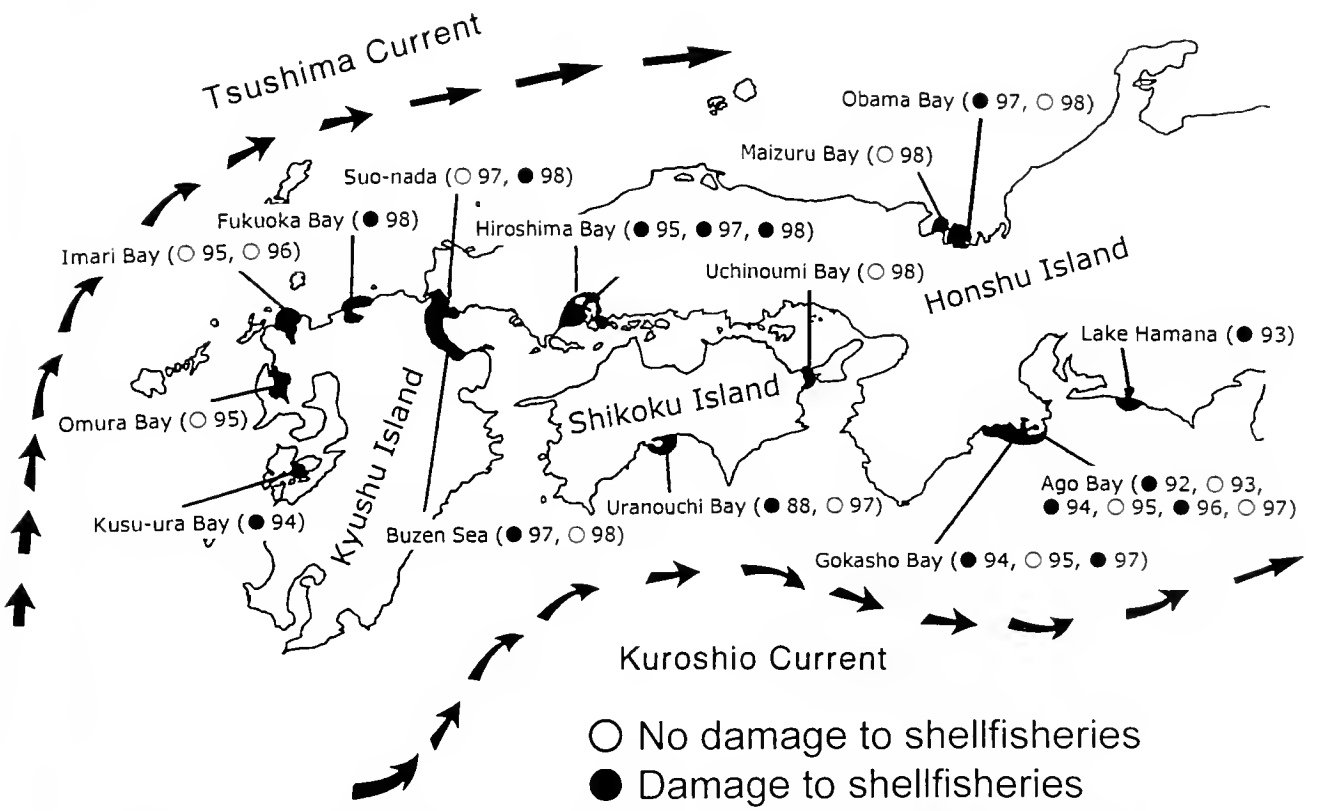

Figure 1. Records of red tide (>10^6 cells L^{-1}) due to *Heterocapsa circularisquama* and two major currents in Japan.

H. circularisquama has also been recorded at Fukuoka Bay in 1989, and at Ago Bay in 1992, resulting in mass mortality of shellfish (Fig. 2).

Until 1998, 28 cases of *H. circularisquama* red tide (maximum cell density $\geq 10^6$ cells L^{-1}), including 14 incidences leading to fisheries damage, had been recorded in 14 locations of western Japan (Fig. 1). The red tide due to *H. circularisquama* has been associated with massive killing of commercially important bivalve species: manila clam *Ruditapes philippinarum*, Pacific oyster *Crassostrea gigas*, pearl oyster *Pinctada fucata*, blue mussel *Mytilus galloprovincialis*, etc. The current proliferation of *H. circularisquama* throughout western Japan has essentially destroyed molluscan shellfish aquaculture. Economic losses of shellfish aquaculture have been estimated to be at least 93 million US dollars in the last decade (Table 1).

On the other hand, there have been no records of death of finfish and crustacean species or public health hazard due to the consumption of shellfish and other seafood products in association with the red tide of *H. circularisquama*. This type of biohazard in marine animals is markedly different from previous reports of damage caused by harmful algae responsible for PSP, DSP, ASP, NSP, ciguatera poisoning, and ichthyotoxicity.

Behavior of Shellfish Affected by H. circularisquama

The effects of *H. circularisquama* on bivalve molluses have been described in previous studies. Matsuyama et al. (1996) have observed that exposure of pearl oysters to $5–10 \times 10^6$ *H. circularisquama* cells L^{-1} resulted in death within several days, although the level of dissolved oxygen was not critical. The dead individuals have been characterized by a marked shrinkage of the mantle, decrease of glycogen lobe attached to the mantle, and gut discoloration. The symptoms clearly reflect the direct cytotoxic effect of *H. circularisquama* on pearl oyster physiology. Similar harmful effects on the oyster *C. gigas* and the mussel *M. galloprovincialis* have been shown during the red tides which have occurred elsewhere (Etou et al. 1998, Matsuyama et al. 1998).

Laboratory Exposure Experiment Using Cultured Material

Nagai et al. (1996) have shown that the mortality of pearl oyster spat caused by *H. circularisquama* depends on the cell density of this alga. Pearl oysters exposed to *H. circularisquama* cells at a density above 10^7 cells L^{-1} have showed vigorous contraction of the mantle and gills, clapping, sustained valve closure, paralysis, and heartbeat stoppage within 24 hours. Furthermore, the mussel

(1) and (2): Light micrographs of *H. circularisquama;* (3) Dead shellfish: mussel *Mytilus galloprovincialis*, razor clam *Solen strictus*, manila clam *Ruditapes philippinarum* due to red tide of *H. circularisquama* (Fukuoka Bay, 1989, photograph is provided by Y. Tanaka); (4) Dead pearl oyster *Pinctada fucata* (Ago Bay, 1992); (5) Dead oyster *Crassostrea gigas* (Hiroshima Bay, 1995); (6) Farming-ground of manila clam *Ruditapes philippinarum* affected by the red tide of *H. circularisquama* (Hiroshima Bay, 1995, Photograph is provided by T. Hamasaki).

TABLE 1.

Damage to fisheries industries caused by harmful algal blooms in Japan.

Causative Agents	Periods	Amount (million $US)
Chattonella spp.	1969–1999	185
Heterocapsa circularisquama	1988–1999	92
Gymnodinium mikimotoi	1972–1999	83
Heterosigma akashiwo	1972–1999	15

M. galloprovincialis significantly reduced its feeding activity when exposed to 10^4 cells L^{-1} of *H. circularisquama*, but not in culture with 10^6 cells L^{-1} of the morphologically similar dinoflagellates *Scrippsiella trochoidea* and *Heterocapsa triquetra* (Matsuyama et al. 1997). Some harmful algae are known to be toxic to marine shellfish. The blooms associated with the unarmored dinoflagellate *Gyrodinium aureolum* and picoplankton *Aureococcus anophagefferens* referred to as "brown tide" lead to considerable failure in mussel and scallop farming (Tangen 1977, Shumway 1990). Laboratory-rearing experiments using these algae have proven considerable detrimental effects on various bivalve species. The harmful effect of *H. circularisquama* on bivalves is very specific and pronounced compared to other harmful algal species.

Harmful Effects of H. circularisquama *on Other Organisms*

Laboratory exposure experiments show that various marine animals such as bivalves, gastropods, solitary acidians, and jellyfish are affected by *H. circularisquama*, unlike vertebrates, crustaceans (lobster, shrimp, crab), starfish, and sea urchins (Table 2). On the other hand, although the occurrence of illness associated with the consumption of bivalves that accumulated *H. circularisquama* cells may be a cause for concern in humans, shellfish poisoning has never been observed in samples collected from red tide areas. Direct HPCL analysis has failed to detect PSP toxins or DSP toxins in the cells of *H. circularisquama*. No death or symptoms have been observed in 5 mice to which a cultured cell pellet of *H. circularisquama* had been injected in intraperitoneally at a rate of 10^6 cells/mouse (Table 2).

TABLE 2.

Effects of *Heterocapsa circularisquama* on various animals.

Animals	cells L^{-1}	Symptoms
Bivalves	10^4–10^5	Feeding inhibition
	$>10^6$	death

Characterization of Heterocapsa circularisquama *Toxicity*

The toxicity of *H. circularisquama* to bivalves has been shown to be mediated by a chemical agent. The toxic effect of *H. circularisquama* on bivalves is not due to extracellular metabolites, cell exudates, and "naked cells" prepared by sonication and centrifugation (Fig. 3A). Furthermore, trypsin and SDS (sodium dodecyl sulfate) treatments have been found to decrease drastically the toxicity of *H. circularisquama* cells (Fig. 3B). Therefore, a labile protein-like complex localized on the cell surface presumably exerts a detrimental effect on bivalves. However, purification and characterization of toxic fractions have not been successful because this agent is highly labile under neutral conditions. Recently, exposure of larval manila clam to *H. circularisquama* has demonstrated acute toxicity on their survival and development, which is associated with a significant increase of intracellular calcium concentration.

SUMMARY

Blooms of the dinoflagellate *H. circularisquama* have been associated with mass mortalities of various bivalves in western Japan since 1988. Toxicity of this species is acute and specific to

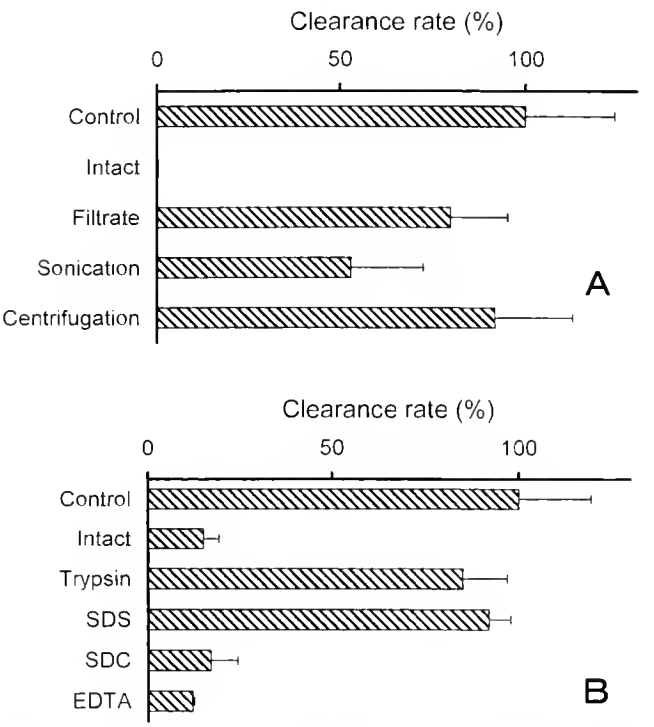

Figure 3. Relative clearance rates of *Mytilus galloprovincialis* feeding to physically (A) and chemically (B) treated *Heterocapsa circularisquama* cells (Control: *Isochrysis galbana*, 8×10^7 cells L^{-1}). Initial cell density of *H. circularisquama* ranged from $2.5–2.8 \times 10^5$ cells L^{-1}. SDS: sodium dodecylsulfate. SDC: sodium deoxycholate. DTT: dithiothreitol. Each chemical was used at a concentration lower than that which would inhibit the swimming of *H. circularisquama*. Error bars show ±S. D.

bivalves and gastropods. Unfortunately, no successful damage prevention strategy has been developed until now. Therefore, relocation and/or early harvest of organism are the only methods to reduce the shellfisheries damage. In some locations, early warning systems by local governments that are based on frequent field monitoring of *H. circularisquama* cells have successfully reduced the shellfisheries damage. *H. circularisquama* blooms do not cause finfish killing and mammals illness. However, a rapid decline of demand for products due to misinformation, rather than actual shellfish poisoning, could occur. On the other hand, toxicity of *H. circularisquama* can easily be reduced when the cells are disturbed with physical and chemical treatments (unpublished). This fact will provide crucial information for improvement of damage prevention in the future.

GILL STRUCTURE, ANATOMY AND HABITAT OF *ANODONTIA EDENTULA*: EVIDENCE OF ENDOSYMBIOSIS

MA. JUNEMIE HAZEL L. LEBATA* AND JURGENNE H. PRIMAVERA
Aquaculture Department, Southeast Asian Fisheries Development Center, Tigbauan, Iloilo 5021, Philippines

ABSTRACT Surveys and interviews were conducted to determine sources and habitat of *Anodontia edentula*. Results showed that they inhabit muddy substrate of mangrove areas or the adjacent mudflats, burying at 20–60 cm deep in the mud. They are strategically situated in the sulfide-rich, low-oxygen layer of the substrate but have access to oxygen through their inhalant tube; both sulfide and oxygen are essential for their survival. Study of the clam's gross anatomy revealed thick, fleshy, deep purple to blackish brown gills; reduced digestive structure; and a highly elastic foot capable of extending several times longer than its body length. These observations conform with the anatomy of fellow lucinid clams. Furthermore, scanning electron micrographs showed coccoid or spherical bacteria occupying bacteriocytes in the clam's gills. Intermediate cells separating bacteriocytes observed in other lucinids were also noted in the SEM.

KEY WORDS: *Anodontia edentula*, anatomy, bacteria, gill, endosymbiosis, habitat

INTRODUCTION

Anodontia edentula (Linné, 1758) is one of the popular bivalves in the coastal areas of central and southern parts of the Philippines. It grows to a maximum size of 8–9 cm shell length (SL), 180–210 g total weight (TW) and is an important source of food and livelihood in coastal areas where it is abundant (Lebata 2000). It is one of the few expensive bivalves in the region as it is being sold per piece and not per kg or container like the common bivalves, i.e. mussels, oysters and scallops. It is a local favorite because of its sweet taste, especially when eaten raw, and men deeply believe in its aphrodisiac properties. Its popularity led to overexploitation as manifested by the decline in catch, in terms of quantity and size, through the years.

A. edentula inhabits sandy-muddy substrate near mangrove areas or the adjacent mudflats (Sotto & von Cosel 1982). It belongs to order Veneroida, family Lucinidae (Poutiers 1998), to which eulamellibranchs containing symbiotic bacteria predominantly belong (Schweimanns & Felbeck 1985).

Animal-bacteria symbioses have been observed in at least five animal phyla but are most widespread among the bivalves (Distel 1998). Symbioses have been observed in marine mollusks thriving in organically rich sediments (Janssen 1992) and hydrogen sulfide-rich habitats such as anoxic basins (Felbeck et al. 1981); seagrass beds (Cavanaugh 1983); mangrove swamps (Vetter 1985, Frenkiel et al. 1996); and sewage outfalls (Felbeck et al. 1981). Numerous studies have been conducted on this aspect in other lucinid species (Berg & Alatalo 1984, Giere 1985, Schweimanns & Felbeck 1985, Vetter 1985, Reid & Brand 1986, Distel & Felbeck 1987, Frenkiel et al. 1996, Gros et al. 1997, Gros et al. 1998). Studies on *A. edentula* have been limited to species identification and description (Sotto & von Cosel 1982, Poutiers 1998), light microscopic observation (Janssen 1992), paleontology (Cooper 1996), and just recently its elemental sulfur content (Lebata 2000).

In the Philippines, the first article on clam symbiosis was presented by Janssen (1992). Common bivalve species such as *Codakia tigerina*, *A. edentula*, and *Fimbria fimbriata* were obtained from the Mactan Island fish market and observed under a light microscope. Samples were fixed and brought to Germany for light and electron microscopy. However, only *F. fimbriata* was studied in detail using electron microscopy. Symbiosis was discussed based on literature review but no actual field observation or laboratory experiments were conducted to prove this in *A. edentula*. A new study conducted by Lebata (2000) showed that the clams have elemental sulfur in their gills. Elemental sulfur, according to Vetter (1985) is stored in the periplasmic spaces of the bacteria and represents a novel inorganic energy reserve for animal-bacteria symbiosis in the absence of sulfide. This may therefore support the claim of Janssen (1992) on the existence of endosymbiosis in this lucinid species.

Considering its potential for aquaculture and the declining state of its population, it is necessary to have a clear understanding of this clam-bacteria relationship before undertaking culture studies in this species. The objectives of this study were to describe the habitat of the clam; to study its gross anatomy and relate it to its habitat; and to check for the presence of bacteria in the gills using scanning electron microscopy.

MATERIALS AND METHODS

Habitat and Collection

Surveys and interviews were conducted from 1995 to1997 in Panay, Guimaras, and Negros islands in central Philippines (Fig. 1) to determine sources and habitat of *A. edentula*. The most accessible area to the laboratory, Brgy. San Roque in Estancia, Iloilo, central Philippines (11°14′N, 123°8′E), was chosen as the field study site and collection site of clams for laboratory studies. The area has been described in Lebata (2000).

A. edentula was collected during the ebb of a spring tide during the day with the help of a clam collector who can recognize the opening of the clams' anterior inhalant tubes (Fig. 1) on the surface of the substrate. A specialized gear made of flattened iron attached to a wooden handle was used in digging the substrate. The tube that led to the clam was then carefully traced. During collection, depth occupied by the clam was measured from the surface of the substrate, and distance from the mangrove forest was noted.

Physico-chemical parameters were monitored *in situ* at 30 cm deep. Temperature was measured using a field mercury thermometer; salinity with an Atago refractometer; pH with WTW pH 192

meter; D.O. with a YSI Model 51B dissolved oxygen meter; and sulfide with a Lovibond photometer PC 22.

For laboratory experiments, collected clams were transported live to SEAFDEC Aquaculture Department in Tigbauan, Iloilo, approximately 160 km from the collection site. During transport, they were placed in plastic baskets cushioned with papers soaked in seawater. Upon arrival in the laboratory, they were placed in 1-ton fiberglass tanks provided with 30–50 cm deep newly collected mangrove mud and seawater (32–35 ppt). Clams were harvested from the tanks as needed.

Anatomy

Several clams were dissected and the gross anatomy studied following Allen (1958). They were then examined for the presence of gut using an Olympus SZ-ST dissecting microscope. This was done because absence or reduction of the digestive system is a common condition in most clams containing endosymbionts in the gills (Giere 1985). Histological sections of the gonad were also made and observed under an Olympus BH2 compound microscope. Live clams were also placed in a glass aquarium provided

with seawater but no substrate to observe the extension and retraction of the foot.

Scanning electron microscopy

Newly collected live clams ranging from 50.5–62.6 mm shell length were transported to the National Institutes of Biotechnology and Applied Microbiology (BIOTECH) at the University of the Philippines, Los Baños, College, Laguna in northern Philippines (Fig. 1) on 13 May 1998 for scanning electron microscopy (SEM). Upon arrival, the biggest clam (62.6 mm SL) was dissected and the gills processed for SEM. The specimens were fixed in 3% gluteraldehyde with 0.1 M cacodylate buffer at ph 6.8 for 3 h, washed with 0.1 M cacodylate buffer 3 times at 15 min each, post-fixed in 1% osmium tetroxide for 1 h, rewashed with 0.1 M cacodylate buffer, dehydrated in graded ethanol series, and substituted with isoamyl acetate. Then they were dried in the Hitachi HCP-2 critical point dryer, mounted on supports, coated with gold and palladium using the Hitachi E101 ion sputter, and viewed under the Hitachi S-500 scanning electron microscope. Photomicrographs of the specimens were taken and compared with scanning electron micrographs of bacteria from other endosymbiont-containing invertebrates (Karl et al. 1980, Fiala-Medioni & Metivier 1986, Fiala-Medioni et al. 1986) and lucinid clams (Berg and Alatalo 1984).

RESULTS

Habitat

A. edentula thrive in the muddy substrate of mangrove areas or the adjacent mudflats. The closer the area to the mangroves the more clams can be harvested (within 20 m from the edge of the forest) and the number of clams collected decreased as collection moved seaward. Previous and recent surveys showed that they are marine and can be found nowhere in rivers or estuaries.

Clams were deeply buried in the mud ranging from 20–60 cm below the surface, but mostly in the deeper portions. Other non-lucinid bivalves inhabiting the area did not bury deeper than 15–20 cm.

The temperature ranged from 27–31°C (mean = 28.7 ± 0.28), the salinity from 32–36 ppt (mean = 34.5 ± 0.31), pH from 5.15–6.55 (mean = 5.95 ± 0.10), dissolved oxygen from 0.2–1.0 ppm (mean = 0.3 ± 0.05), and sulfide 1.5–30.0 μM (mean = 25 ± 1.78).

Anatomy

A. edentula is rounded and globose with an inflated, thin, brittle shell having irregular concentric growth lines. The shells are equivalve and the umbones are pointing anteriorly. Removing either valve, the mantle is first exposed, and removing further the mantle, the thick, fleshy, deep purple to blackish brown gills are exposed. The gills have right and left demibranchs which cover the posterior two-thirds of the gonad. On the ventral side of the latter, a little behind the posterior half, the relaxed/retracted foot is attached (Fig. 2a). So the gonad is the core of the clam, being partially covered on both sides by the gills, which are both fully hidden under the mantle. These three, plus the foot are the most prominent organs in the clam.

The foot of the clam, as observed in aquaria without mud, can extend up to 15–20 cm long and can expand to 0.8 cm in diameter (Fig. 2b). It is capable of moving around, creeping on the aquarium surface or moving up to the maximum distance its tip can reach in the water column.

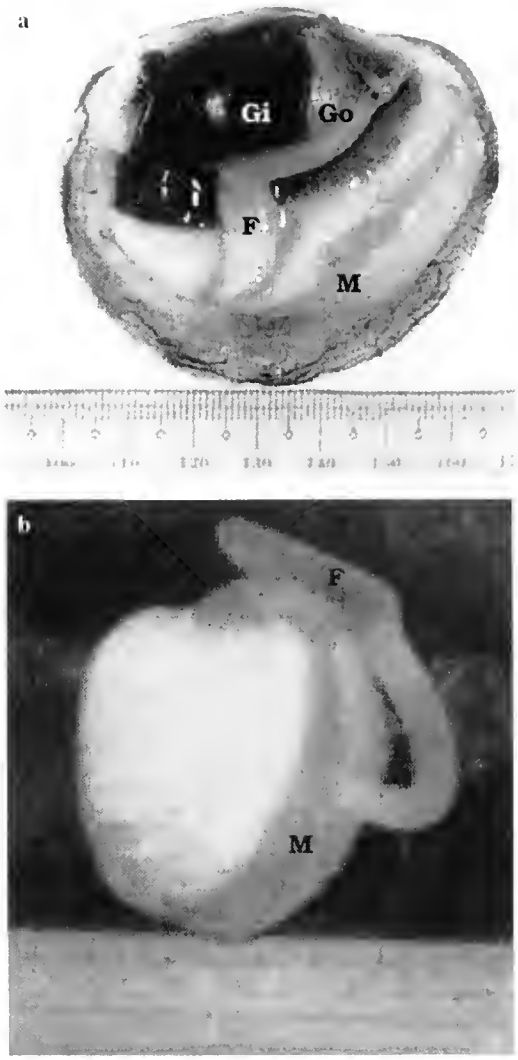

Figure 2. (a) Anatomy of a newly dissected *Anodontia edentula* showing its major organs (M: mantle, Gi: gills, F: foot, Go: gonad) after removing the right valve and the right mantle. Note the size of the relaxed foot. (b) Extended foot of live *Anodontia edentula* as seen inside a glass aquarium provided with seawater but no mud.

Dissection showed a very simple gut. The mouth enters as a slit on the anterior end of the gonad. The intestine coils inside the gonad and passes out dorsally into the rectum which lies above the dorsal side of the mantle and out to the body cavity. Efforts were made to remove the whole gut separately from the other tissues, especially the digestive structure. However, all the animals examined had developing or mature gametes. This hindered the process of tracking the very minute intestines (the biggest being 1 mm dia.) inside the gonads (Fig. 3). Unlike in other clams where the stomach is a prominent structure, no distinguishable stomach was observed in this species. Histological sections of juvenile and adult clams similarly revealed the absence of a well-defined stomach structure and the coiling inside the gonad of very small (less than 1 mm dia) intestines (Fig. 3).

Scanning electron microscopy

Scanning electron micrographs showed that bacteria in bacteriocytes (Fig. 4c) were spherical with a dia. of 8–11 μm.

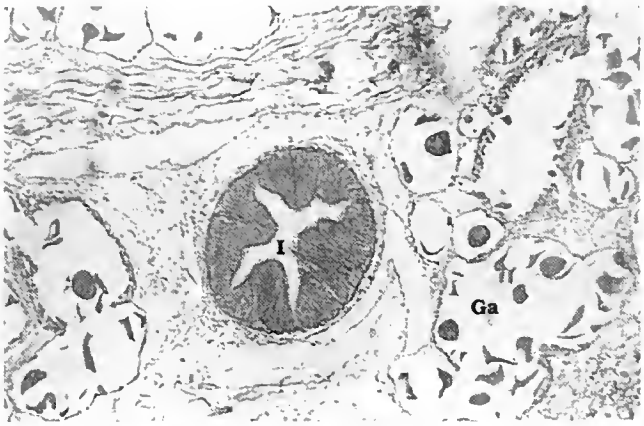

Figure 3. Cross section of *Anodontia edentula*'s intestines inside its gonad (I: intestine, Ga: gametes).

The anatomy of lucinid gills described by Distel and Felbeck (1987) may be representative for all members of family Lucinidae, and also best describes the gill anatomy of this species. Each of the two demibranches (Fig. 4a) is composed of inner and outer lamellae separated by interlamellar space. Each lamella is divided into three zones—the ctenidial filament zone, transition zone, and bacteriocyte zone. The ctenidial filament zone is the outermost zone and composed of ctenidial filaments (Fig. 4b). The innermost bacteriocyte zone (Fig. 4c) housing the bacteria lines the interlamellar space of the inner and outer lamellae. Each bacteriocyte is separated by intermediate cells devoid of bacteria (Fig. 4c).

DISCUSSION AND CONCLUSION

Surveys and salinity readings (34.5 ± 0.31 ppt) showed that *A. edentula* prefer the marine environment. They live in slightly acidic (5.95 ± 0.10) substrate which is quite anoxic. The habitat is sulfide-rich at 25 ± 1.78 μM (or 22.5 μM H_2S at pH 6.0). Sulfide measurements were higher compared to concentrations (7 ± 14.0 μM) obtained by Bagarinao and Lantin-Olaguer (1998) from 5 cm deep mud in a mangrove estuary in Guimaras Island. These concentrations are inhospitable to other aquatic non-endosymbiotic organisms as shown in the review paper of Bagarinao (1992). However, for endosymbiotic clams this may be ideal. According to Distel and Felbeck (1987), the clams should be strategically situated in an interface between a sulfide-generating zone (anoxic) and water with sufficient oxygen (oxic). The location of *A. edentula* (20–60 cm deep in mangrove mud) may allow it direct access to sulfide, and the inhalant tube provides access to oxygenated water; both sulfide and oxygen are essential for its survival.

The anatomy of the clam further supports endosymbiosis. The foot of *A. edentula* can extend up to several times longer than its shell length. Just like other lucinids, this gives it the capacity to construct a ventilation burrow (Reid & Brand 1986) and allows it to draw water from the surface (Dando et al. 1985). The tip of the foot is specialized for the construction of this inhalant tube. It is provided for with glands that lay down mucus for the building of the tube (Allen 1958). In cases where sulfide is limiting, Childress et al. (1991) have proven that the foot can dig deeper and is responsible for the uptake of sulfide from deeper parts of the substrate. Sulfide is taken up across the foot of the clam and into the blood that transports it to the gills. The host is therefore responsible for delivering the sulfide to the bacterial symbiont.

Sulfide is a highly reduced energy molecule, and a variety of biological systems have evolved to oxidize sulfide in orderly enzyme-regulated steps to harness the energy and avoid poisoning (Bagarinao 1992). In a clam-bacteria symbiosis, bacteria are assumed to provide the mollusk with chemosynthetically fixed carbon dioxide via aerobic oxidation of sulfide (Vetter 1985). Oxidation of sulfides and other reduced sulfur compounds provides

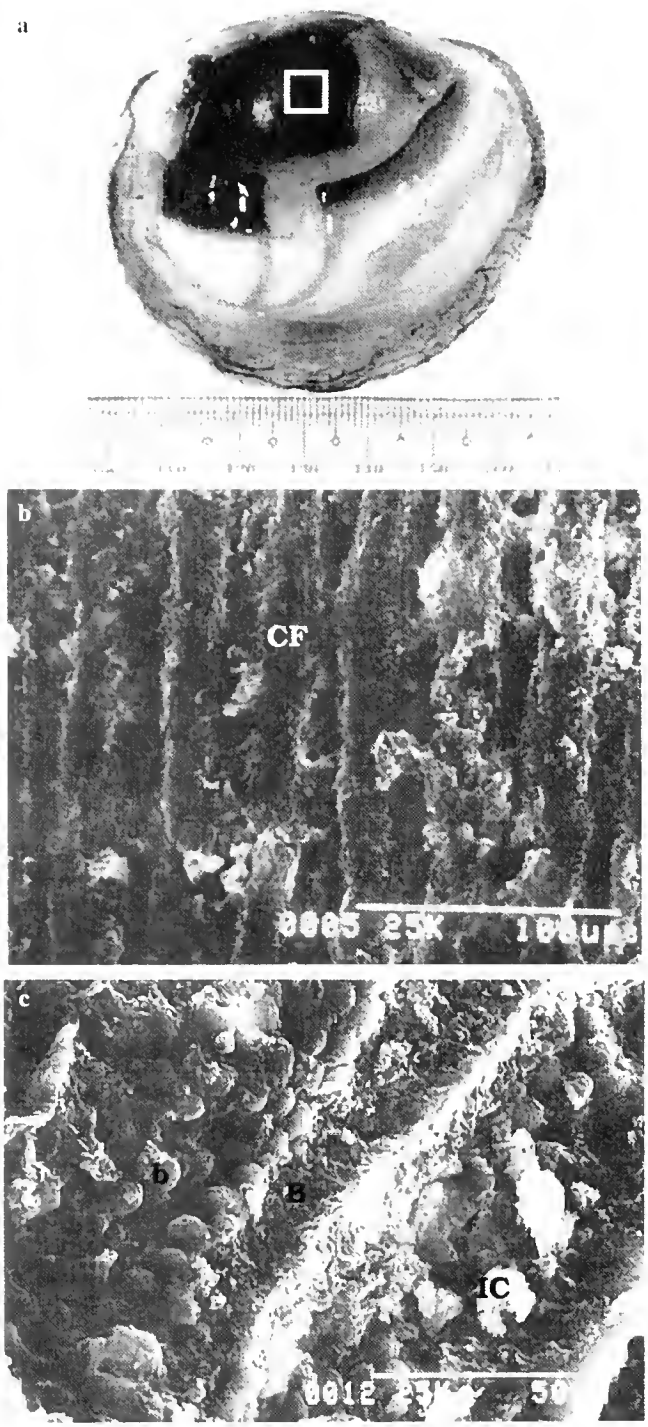

Figure 4. Gill structure of *Anodontia edentula* taken under scanning electron microscope. (a) Portion of the gill's right demibranch (boxed) cut for SEM. (b) Scanning electron micrograph of the boxed region showing the ctenidial filaments (CF). (c) Boxed region rotated 90° about its horizontal axis, exposing the bacteriocytes (B) housing the spherical endosymbiotic bacteria (b). Note also the presence of intermediate cells (IC) devoid of bacteria.

energy to the bacteria to fix carbon dioxide into organic compounds which become available to the host clam (Distel & Felbeck 1987, Kelly & Harrison 1989). The Calvin cycle is the main metabolic pathway used by the bacteria to convert carbon dioxide to organic carbohydrates powered by the energy (ATP) generated from the oxidation of sulfides (Distel 1998). In the process of oxidation, sulfide is converted into elemental sulfur and stored for future use (Childress & Mickel 1982, Vetter 1985, Distel 1998).

Dissection and histological examination revealed a very simple gut (Fig. 3), similar to that observed for other lucinid species, *Codakia orbicularis* (Berg & Alatalo 1984), and *Parvilucina tenuisculpta* (Reid & Brand 1986). This condition also parallels the observation of Allen (1958) in several genera (*Codakia, Divaricella, Loripes, Lucina, Myrtea* and *Phacoides*) belonging to family Lucinidae.

The stomach and some parts of the intestines outside the gonad were observed in some members of the families Pectinidae, Ostreidae, Pinnidae and Corbiculidae examined by Okutani et al. (1985). Ruppert and Barnes (1994) also described the clear digestive diverticula and stomach outside the gonads in *Pecten* and other filter feeders. The well-defined digestive systems in these families contrasted the very simple and reduced digestive structures in *A. edentula* and other lucinid species.

According to Giere (1985), gut reduction is a common condition in most clams containing endosymbionts in the gills. The great reduction or absence of a digestive system in the host species indicates that bacterial chemosynthesis is vital to the host's nutritional scheme (Distel & Felbeck 1987, Distel 1998). Hence, gut reduction in *A. edentula* is further evidence of an endosymbiotic relationship.

Furthermore, the gills of *A. edentula*, described to be thick, fleshy and deep purple to blackish brown in color, characterize the gills of endosymbiotic clams which were noted for being thick and opaque, contrasting sharply the thin, delicate, translucent gills of most bivalves (Distel 1998). This agrees with the description of Allen (1958) for several genera of lucinids, Dando et al. (1985) for *Myrtea spinifera*, and Distel and Felbeck (1987) for *Lucinoma aequizonata, Lucinoma annulata*, and *Lucina floridana*, all of which are known for endosymbionts. Similarly, Felbeck et al. (1981) observed the same gill coloration in bivalves collected from sulfide-rich habitats containing sulfide oxidation enzymes in contrast with the small light-colored gills of those lacking these enzymes. According to Distel and Felbeck (1987), the dark coloration and thickness of the gills are due to the presence of a thick layer of subfilamentar tissue perforated by regular arrays of bacteriocyte channels formed by bacteriocyte cylinders containing the bacterial symbionts. The nearly black appearance of the gills may also be attributed to cytoplasmic hemoglobin (Kraus & Wittenberg 1990). Although it is relatively uncommon in symbiont-free gills, cytoplasmic hemoglobin is a nearly constant feature in symbiont-harboring gills of bivalves and may function in the delivery of oxygen and sulfide to ensure symbiont autotrophy and host cell respiration (Kraus 1995).

Scanning electron photomicrographs showed only one type of bacteria in the bacteriocyte zone of the gills (Fig. 4c). The bacteria were coccoid and almost of uniform sizes. According to Dando et al. (1985) and Conway et al. (1992), only one type of endosymbiont exists in every clam host, and that bacterial pleomorphism may only represent varying developmental stages of a single species of symbiont.

The absence of bacteria in the mantle and foot and their confinement in the gills may be explained by the role of the gills in gas exchange. The bacteria must therefore thrive in the gills to ensure access to oxygen and sulfide obtained from the substrate. Doeller et al. (1988) isolated two different hemoglobins occurring in nearly equal concentrations in the gills of *Solemya velum*. The sulfide reactive hemoglobin delivers sulfide to the bacteria and the non-sulfide reactive one delivers oxygen. Aside from their role in gas exchange, the presence of bacteriocytes (which are absent in the mantle and foot) made the gills suitable for bacterial settlement.

Scanning electron micrographs showed that the morphological appearance of bacteria in gill samples resembles those observed by Berg and Alatalo (1984) from the gills of a lucinid, *C. orbicularis*, and in other endosymbiont-containing invertebrates (Karl et al. 1980, Cavanaugh et al. 1981, Fiala-Medioni & Metivier 1986, Fiala-Medioni et al. 1986). The measured size of the bacteria (8–11 μm) is in the same range as those observed for *S. velum* (2–10 μm: Cavanaugh 1983), *Anodontia philippiana, Lucina multilineata, Lucina costata* and *Lucina radians* (maximum of 8.9 μm: Giere 1985), *L. aequizonata* and *L. annulata* (5–10 μm: Distel & Felbeck 1987), and *Solemya borealis* (3–15 μm: Conway et al. 1992). The presence of intermediate cells separating bacteriocytes was also noted by Giere (1985) in 4 species of lucinids collected from Bermuda. The bacteria and the gill structure observed under SEM agree with observations of other papers as described by the literature in previous paragraphs and may be strong supporting evidence to prove clam-bacteria endosymbiosis in *A. edentula*.

As supported by its habitat, anatomy, and the bacteria in its gills, we cannot consider *A. edentula* to be an ordinary mangrove clam. Its endosymbiotic capacity should be considered in future studies, whether on its biology or culture.

SHELL MORPHOGENESIS OF SEVERAL VENERID BIVALVES

GEORGE A. EVSEEV, NATALYA K. KOLOTUKHINA, AND OLGA YA. SEMENIKHINA*
Institute of Marine Biology, FEB RAS, Vladivostok 690041, Russia

ABSTRACT Morphogenetic series of venerids *Protothaca euglypta*, *Ruditapes philippinarum*, and *Callista brevisiphonata* were constructed to determine the morphological criteria for identification of their larvae and juveniles from 0.2 up to 1.5–2.0 mm shell length. Larvae, post-larvae, and juveniles were reared in the laboratory and collected from plankton and benthic samples. The important distinguishing characters (shell outlines, provincular denticles, sequence of cardinal teeth formation, recapitulative sculpture, and others) of venerid bivalves in different stages of development are presented. Morphogenetic series can provide the basis for the phylogenetic reconstruction and be a successful aid in solving the problems of identification and ecology of bivalves in early stages of their ontogeny.

KEY WORDS: veneridae, *Protothaca*, *Ruditapes*, *Callista*, morphogenesis, hinge, larval-juvenile morphological features

INTRODUCTION

Venerids are a common group of bivalves in the northwestern part of the Sea of Japan. There are 10 venerid species in this area. The taxonomic differences, vertical and spatial distribution patterns, density, and reproductive ecology of these clams are relatively well studied (Habe 1951, Habe 1977, Scarlato 1981, Ponurovsky 1993, Sato 1999). However, these studies are largely concerned with adult animals. Little information is available on the pelagic stages of some taxa and juveniles (Kulikova & Kolotukhina 1989), which considerably differ from adults in their morphology. A lack of efficient criteria by which to discriminate among venerid bivalves in early juveniles (~0.3–3 mm shell length) hinders the studies of their recruitment both in natural populations and on artificial substrata. At the same time, almost all of these clams are objects for harvesting and, potentially, cultivation in the Sea of Japan. The purpose of our study is to determine the morphological criteria for the identification of three common venerid species in early stages of their ontogeny.

MATERIALS AND METHODS

Adult *Protothaca euglypta* (Sowerby, 1914), *Ruditapes philippinarum* (Adams et Reeve, 1848), and *Callista brevisiphonata* (Carpenter, 1865) from the northwest Sea of Japan, their larvae, post-larvae, and juveniles were used in this study. Adults and juveniles were sampled by SCUBA-diving in different biotopes down to 20 m depth. Larvae of *R. philippinarum* and *C. brevisiphonata* were collected on a 96-μm nylon plankton net from a small boat. Larvae and juveniles of *P. euglypta* were reared in the laboratory and picked out from benthic samples. Laboratory specimens were kept using the appropriate methods (Loosanoff & Davis 1963) and fed with *Isochrysis galbana*, *Chaetoceras muelleri*, and *Dunaliella salina*.

Larval and juvenile shells were cleaned in a 5–10% solution of sodium hypochlorite, disarticulated with a fine needle, rinsed with distilled water, and embedded in glycerin jelly for light microscopy. Morphogenetic series of two types were constructed. Progressive series consisted of larval stages up to the juvenile and

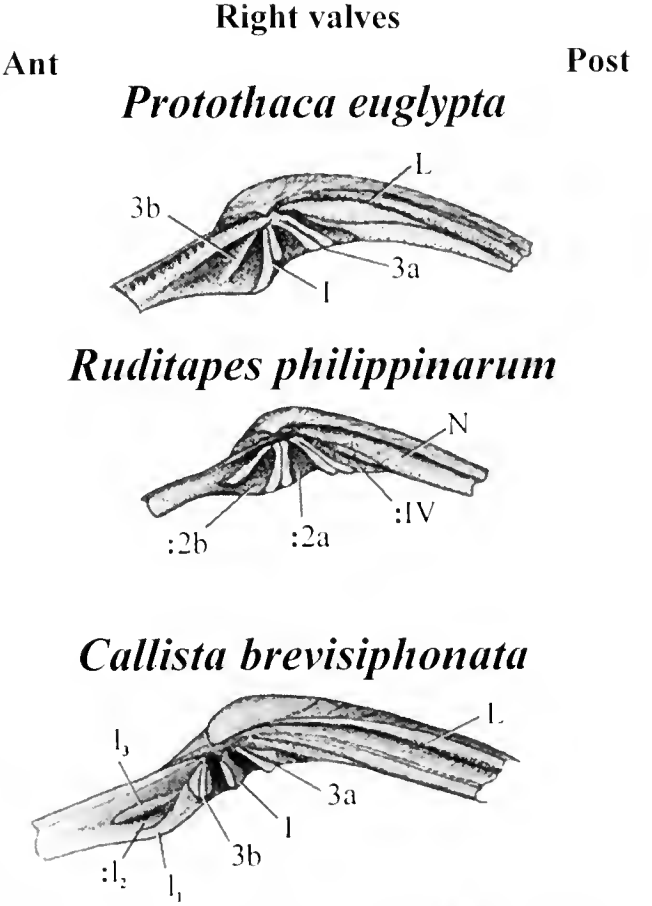

Figure 1. Hinge-tooth nomenclature of venerid shells (after Bernard, 1895 and Le Pennec, 1980, with alterations). Roman numerals, Arabic numerals followed by a lower case letter, and letters followed by subscript numerals indicate developing hinge teeth. I, the first tooth of the right valve; :IV, pit for the second tooth of the left valve. 3a, the initial tooth of tooth III of the right valve; 3b, the secondary tooth of tooth III; :2a and :2b, pits for the initial and secondary teeth of tooth II of the left valve. I_1, the first lateral tooth of the right valve; I_3, the second lateral tooth of the right valve; $:I_2$, pit for lateral tooth of the left valve. Ant, anterior; Post, posterior; L, ligament; N, nymph.

adult stages, and retrospective series consisted of adults to juveniles including early post-larval stages. A system of hinge-tooth notation used in this study (Fig.1) is based both on Bernard's (1895) nomenclature and comments of Le Pennec (1980).

RESULTS

The examined distinguishing morphological features of three venerid species are summarized in Table 1.

A series of *P. euglypta* (Fig. 2) begins with pelagic larvae of 200 μm shell length. The larval shell is almost regularly rounded and equilateral. The umbones are high and the distinct ligament pit is posteriorly situated. There are 7–8 well-developed rectangular provincular denticles that elongate as the shell grows.

At a shell length of 210–260 μm cardinal teeth form. At first, tooth II appears as an oval knob on the narrow and elongate plateau in the antero-dorsal part of the left valve. On the right valve, cardinal tooth I forms at a shell length of more than 240–260 μm. Similar to tooth II, tooth I is placed on the dental plateau in the anterior part of the valve. Initially, this tooth is rounded.

At a shell length of 250–400 μm, the anterior end of the shell is longer than the posterior end and the umbones are higher than in the previous stage. The number of provincular denticles remains nearly unchanged, but their shape becomes more ventrally elongate. The dental plateau of tooth II of the left valve is broadened and elongated, and the new bulge develops in the antero-ventral part of tooth II. This bulge develops into a high knob that is separated from tooth II by a marked saddle. Tooth II acquires a bicuspidate shape.

On the right valve, tooth I becomes high and its shape changes to oval. Its plateau is broadened posteriorly and ventrally. The new dental plateau of cardinal tooth III develops on the surface of first plateau between tooth I and the anterior end of the provinculum. The outer shell surface bears 2–3 concentric ridges that are more distinct at the posterior field of the shell.

At a shell length of 400–600 μm, the provincular denticles and ligamental pit are overgrown by the plateau of teeth I and III. At the outer posterior end of the shell, 1–2 low concentric ridges appear as the initial stage of the separation of the escutcheon. The lunule formation may also occur in this stage of development.

At a shell length of 600–900 μm, a new bulge develops along the dorsal margin of the dental plateau of tooth III. This bulge is elongated and connected with the base of tooth III. Tooth III consists of two parts: the ventral part 3a and the anterior part 3b. At the ligamental pit, a new broad tooth pit appears that is anteriorly limited by tooth 3a. The posterior and dorsal parts of this pit are occupied by an internal ligamental layer (resilium). The anterior part of the pit is intended for tooth IV of the left valve. The posterior end of the shell becomes thicker, and the formation of the escutcheon takes place there. The outer shell surface bears several high concentric ridges. In addition to these ridges the radial ribs develop, and the formation of the external ligament is completed at 900–1500 μm shell length.

The series of *R. philippinarum* (Fig. 3) begins at the larval stage of 230 μm shell length. The provicultum bears 12–14 small irregular denticles. The shell is inequilateral; the anterior end of the shell is almost straight and slightly longer than the posterior end. The umbones are broad and low, and the distinct ligament pit is posteriorly located.

At a shell length of 250–350 μm, the dental plateaus of cardinal teeth I and II begin to form. Tooth II appears first, and when the shell length is approximately 300 μm, it is clearly seen as an oval and high knob at the margin of its dental plateau. On the right valve, dental plateaus of teeth I and III develop at this stage. The

TABLE 1.

Morphological features of larval and juvenile venerid bivalves (for the right valves).

Stage	Species		
	Protothaca Euglypta	*Ruditapes Philippinarum*	*Callista Brevisiphonata*
180–300 μm	Shell high and equilateral, with 7–8 regular denticles; ligament pit distinct; outer surface with growth lines.	Shell inequilateral, with 12–14 small irregular denticles; ligament pit distinct; outer surface covered with concentric striation.	Shell oval, slightly inequilateral, without any denticles; ligament pit indistinct; outer surface with fine and irregular concentric grooves.
250–350 μm	Formation of cardinal tooth I; outer surface covered with concentric growth lines.	Formation of dental plateau for cardinal teeth I and III; outer surface with weakly waved concentric and regular grooves.	Formation of cardinal tooth III; overgrowing of ligament pit; formation of dental plateau for cardinal tooth I; outer surface with nearly regular concentric grooves.
350–600 μm	Formation of cardinal tooth III; overgrowing of ligament pit; outer surface with widely spaced concentric ridges.	Formation of cardinal tooth I; overgrowing of ligament pit; outer surface with regular concentric grooves and widely spaced radial striae.	Formation of cardinal tooth I; bifurcation of tooth III into 3a and 3b; formation of external ligament; outer surface with nearly regular concentric grooves.
600–900 μm	Bifurcation of tooth III into 3a and 3b; formation of ligament-and-tooth pit :IV; formation of escutcheon; outer surface with concentric ridges.	Formation of cardinal tooth III and ligament-and-tooth pit :IV; outer surface with concentric grooves and radial ribs.	Formation of lateral tooth I_1.
900–1,500 μm	Formation of external ligament; outer surface with concentric ridges and radial ribs.	Bifurcation of tooth III into 3a and 3b; formation of external ligament.	Formation of lateral tooth I_3.

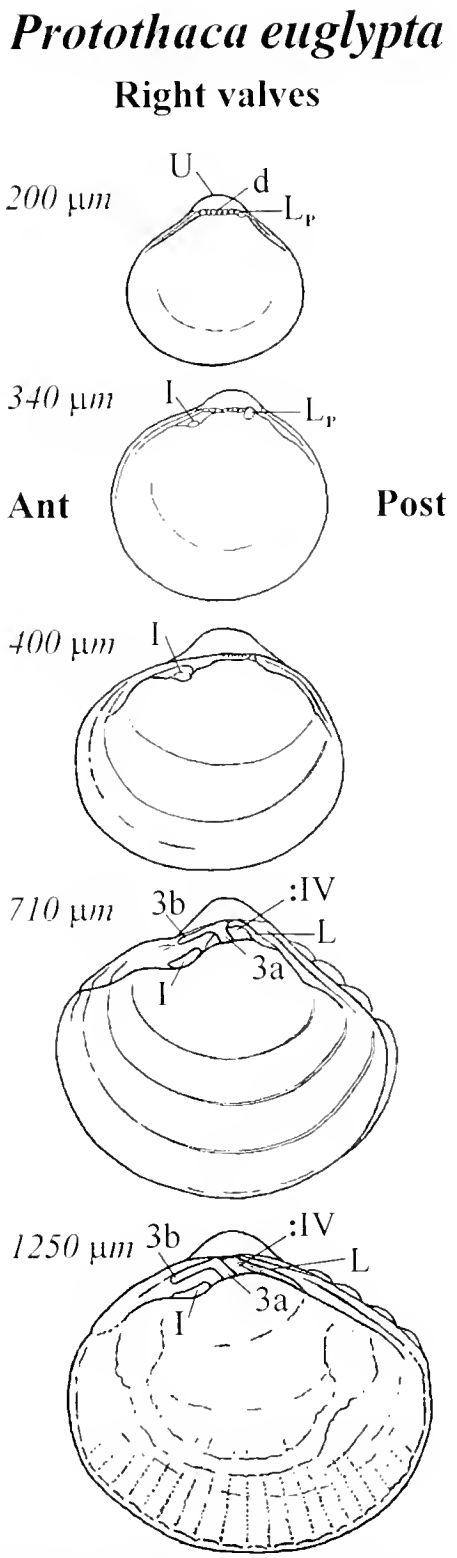

Figure 2. Morphogenetic series of *Protothaca euglypta*, the Sea of Japan. Abbreviations and numerals are the same as given in Figure 1. d, provincular denticles; L_p, ligament pit; U, umbo. Shell lengths are given.

outer shell surface is covered with weakly waved concentric and regular grooves.

At a shell length of 350–600 μm, cardinal tooth I develops. The internal layer of the shell appears at this stage. At the next stage (600–900 μm), cardinal teeth III and IV appear. The shell surface has both concentric grooves and radial ribs. There are approximately 28–32 ribs.

At 900–1,500 μm, the shell outlines become more anteroposteriorly elongate. Teeth II and III bifurcate into 2a and 2b and 3a and 3b, respectively. On the posterior side of the ligament-and-tooth pit :IV the external ligament develops. On the internal layer of shell, the scars of anterior and posterior adductors and the pallial line appear. The number of distinct radial ribs of shell surface varies from 30–32 to 38–42. In the first case, the ribs are flattened, low, and smooth or weakly waved. Near the shell margin the ribs are 40–60 μm wide; the width of the intercostal grooves does not exceed 10–15 μm. In the latter case, the ribs are high, broadly spaced (20–30 μm), and have nodular tops. In both cases, rare concentric bridges may appear in the posterior and sometimes in the central area of the shell. The distance between these bridges is about 110–140 μm.

Larval shells of *C. brevisiphonata* 220–240 μm long (Fig. 4) are devoid of any provincular denticles. The shell is oval and slightly inequilateral. The umbones are low and the ligament pit is indistinct. The shell surface looks smooth and lustrous. The formation of the cardinal teeth begins at a shell length of 250–350 μm with the appearance of tooth II on the left valve. Then, tooth III and the dental plateau for tooth I appear on the right valve. Tooth I is the last to form at this stage. The outer surface is covered with nearly regular concentric grooves.

At a shell length of 400–600 μm, tooth III bifurcates into 3a and 3b teeth. The external ligament begins to develop on the posterior side of pit :IV, and its formation is completed when shell length exceeds 800–900 μm. The escutcheon and lunule are indistinct.

At a shell length of 600–900 μm, the first lateral tooth appears, and the second one forms at 900–1,000 μm shell length. The formation of lateral teeth ceases at a shell length exceeding 1,500 μm. The new internal shell layer appears at a shell length of more than 1,000 μm.

DISCUSSION

There are 10 venerid species in the northwestern part of the Sea of Japan (Fig. 5). Adult forms of these taxa have distinguishing morphological features (Scarlato 1981). The constructed morphogenetic series are representative of the clearly distinctive characteristics of larval and juvenile *P. euglypta*, *R. philippinarum*, and *C. brevisiphonata*. Morphogenetic series of other venerid species are not complete. Some of the reasons for this include the comparative rareness of larval and post-larval stages in plankton and benthic samples and difficulties with spawning of adult venerids and rearing of their larvae in the laboratory. Nevertheless, a number of available shells would be sufficient to identify these species. For example, juvenile *Mercenaria stimpsoni* (Gould, 1861) has a wide dental plateau of tooth III, the sculpture with ridges and the comparatively thickened shell on which this species differs from other venerids of the Sea of Japan. Juveniles of *Saxidomus purpuratus* (Sowerby, 1855) possess lateral teeth but differ from *C. brevisiphonata* in their sculpture. The shell outlines of *Liocyma fluctuosa* (Gould, 1841) at a shell length less than 1,000–1,200 μm are close to those of *C. brevisiphonata*; however, the shell surface of *L. fluctuosa* is smooth and lustrous, and lateral teeth are lacking.

The most noticeable differences among adult *P. euglypta*, *Protothaca jedoensis* (Lischke, 1874), and *Callithaca adamsi* (Reeve,

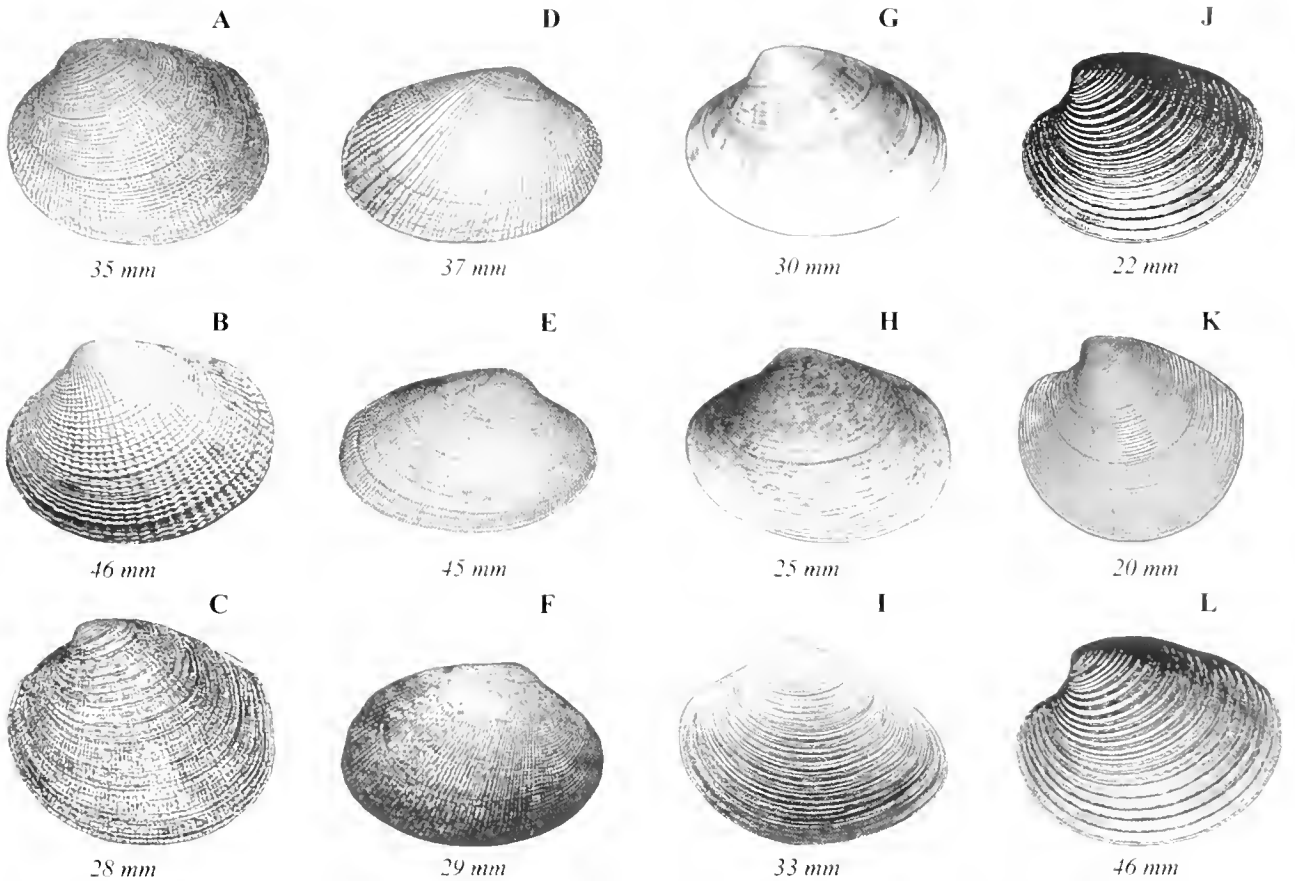

Figure 5. Venerid species of the Sea of Japan and venerids from the Sea of Okhotsk and the South China Sea, given for comparison: (A) *Protothaca euglypta* (Sowerby, 1914), Krasnaya Skala Bight, the Sea of Japan; (B) *Protothaca jedoensis* (Lischke, 1874), Vostok Bay, the Sea of Japan; (C) *Callithaca adamsi* (Reeve, 1863), Vladimir Bay, the Sea of Japan; (D) *Ruditapes philippinarum* (Adams and Reeve, 1848), Krasnaya Skala Bight, the Sea of Japan; (E) *Ruditapes philippinarum* (Adams and Reeve, 1848), the southern coast of Kunashir Island, the Sea of Okhotsk; (F) *Ruditapes philippinarum* (Adams and Reeve, 1848), Ho-Man Island, the South China Sea; (G) *Callista brevisiphonata* (Carpenter, 1865), Sivuchjya Bight, the Sea of Japan; (H) *Saxidomus purpuratus* (Sowerby, 1855), Amursky Bay, the Sea of Japan; (I), *Liocyma fluctuosa* (Gould, 1841), Uspeniya Bight, the Sea of Japan; (J) *Mercenaria stimpsoni* (Gould, 1861), Pogranichnaya Bight, the Sea of Japan; (K) *Phacosoma japonica* (Reeve, 1850), Sivuchjya Bight, the Sea of Japan; (L) *Dosinella angulosa* (Philippi, 1847), Ussury Bay, the Sea of Japan. Shell lengths are given.

1863) (Fig. 5, A–C) concern the shell outlines and sculpture (Scarlato 1981). At the same time, these features are retraced up to 3–5 mm shell length at the retrospective morphogenetic series. The outlines of smaller juvenile shells vary to a considerable extent, but their sculpture, which is the characteristic of specific rank, is comparatively uniform. In this case, the additional information concerning geographical distribution, nature of biotope, periods of spawning and settlement can be useful for the taxonomic differentiation of juvenile stages of *P. euglypta*, *P. jedoensis*, and *C. adamsi*.

A peculiarity of venerid species of the Sea of Japan is that they all are classified into different genera except for two species of genus *Protothaca* (Kafanov 1991). Because of this, the specific features of adult venerids often reveal the characteristics of a higher rank, generic or familial, including shell outlines, availability or lack of marginal crenulation, radial or concentric ribs, and other characteristics (Scarlato 1981, Harte 1998). At the same time, the outlines and height of cross-sections of the ribs and size of intercostal spaces are usually considered as specific characteristics (Tchang et al. 1960, Zhuang 1964, Matsukuma 1986). In connection with these differences, it is often difficult to determine the taxonomic rank of juveniles and to compare them with taxa from other areas. For example, the comparison of post-larval stages of *M. stimpsoni* from the Sea of Japan with Atlantic species *M. mercenaria* (Goodsell et al. 1992) shows that shell outlines may be of a generic rank. However, taking into account the availability of subspecies of *M. mercenaria*, this characteristic might be considered intraspecific.

Similarly, the introduced Atlantic species *R. philippinarum* considerably differs from *Ruditapes decussata* in the morphology of the juvenile hinge (Le Pennec 1980). Unfortunately, the shell sculpture, which is one of the principal features of specific rank, was not considered in that study. At the same time, juvenile *R. philippinarum* from the Sea of Japan have both the recapitulative concentric sculpture and the sculpture of adults (Fig. 3). The former develops at the early post-larval stage and is an important taxonomic characteristic of probably generic rank. At a shell length of 500–600 μm, the concentric sculpture changes to a radial one of two types that can also be seen in adults (Fig. 5, D and E). There are two points of view about the taxonomy of this species. In one opinion, molluscs having this different sculpture may belong to two different species (Tchang et al. 1960, Golikov & Scarlato 1967). In the other opinion (Oniwa et al. 1988), they may be of the same species, revealing the intraspecific latitudinal variability typical of the family Veneridae (Tanabe and Oba 1988, Sato 1996, Sato 1999). Taking into account the morphological differ-

ences of juvenile and adult *R. philippinarum* (Fig. 5, D–F), we are inclined to the first opinion and suggest that the taxonomy of this species inhabiting the wide area from the southern part of the Sea of Okhotsk to the waters of northern New Guinea be revised.

Based on the results of this study, construction of morphogenetic series that are representative of specific features of ontogeny and phylogeny of bivalves would appear to be useful for comparison of characteristics of larval and post-larval development of closely related species and their identification. In this case, the most important characteristics are shell outline; sequences of cardinal and lateral teeth formation; duration of teeth formation when they are not yet functional; formation and then overgrowing of such structures as recapitulative sculpture, internal ligament or ligament pit, or provincular denticles; and sequences of the formation of sculpture, external ligament, posterior–dorsal ridge and escutcheon, shell internal layer, sinus of pallial line, and pigment spots. Morphogenetic series can provide the basis for phylogenetic reconstruction and detailed analysis of the level of supergeneric taxa. Morphogenetic series make it possible to reveal the regularity of recruitment, to estimate the mortality of age cohorts in different stages of ontogeny and in different biotopes, and to solve a number of other ecological problems usually concerning only adults because of the difficulties of identification of species in early stages of ontogeny.

ACKNOWLEDGMENTS

We are very grateful to Dr. Nina A. Aizdaicher, who supplied us with a diatom culture. We express hearty thanks to Ms. Vera S. Mun for technical assistance in the separation of bivalves from benthic samples. Our special thanks to Dr. Alexander I. Pudovkin and Mrs. Tatyana N. Koznova for their help with editing the English manuscript.

THE IMPACT OF RISK INFORMATION ON THE DEMAND FOR GULF OF MEXICO AND CHESAPEAKE OYSTERS

WALTER R. KEITHLY, JR.* AND BAMADY DIOP

Coastal Fisheries Institute, SC&E, Wetland Resources Building, Louisiana State University, Baton Rouge, Louisiana 70803

ABSTRACT The public, through information tied to warning labels and media attention, has been increasingly made aware of the possible health risks associated with the consumption of raw oysters harvested from the Gulf of Mexico. The purpose of this paper is to determine whether this information has reduced demand for the Gulf of Mexico product, the subject of the information, and a closely related product: oysters harvested from the Chesapeake. Results suggest that the information (i.e., warning labels and related media attention) has resulted in a reduction in demand for these products. As a result of the decline in demand, the Gulf of Mexico price was estimated to be about 45% lower than it would have been in the absence of the information. The Chesapeake price was estimated to be almost 15% below what it would otherwise have been.

KEY WORDS: *Vibrio vulnificus*, Gulf of Mexico, Chesapeake, oyster demand

INTRODUCTION

The oyster industry operates on both the East and the West Coasts of the United States. Landings from the East Coast (i.e., the Atlantic estuaries and Gulf of Mexico), dominated by the species *Crassostrea virginica* (Eastern oyster), averaged 28 million pounds annually during 1993–1997 (National Marine Fisheries Service 2000). Landings from the West Coast (i.e., the Pacific estuaries), dominated by the species *Crassostrea gigas*, averaged about 10 million pounds annually during the same period.

Vibrio vulnificus is a natural bacteria species that grows in the warmer waters of the Gulf of Mexico (hereafter referred to as the Gulf). Consumption of raw oysters contaminated with *V. vulnificus* can cause illness and death among the small segment of the population with weakened immune systems. As noted in a recent issue of the *Nutrition Action Healthletter* (Corcoran 1998): "[e]very year, more than 50 people become ill—and at least 10 die—after eating uncooked Gulf of Mexico oysters that are contaminated with *Vibrio vulnificus* bacteria." The presence of *V. vulnificus* in oysters is highly correlated with water temperature in the Gulf and increases significantly during the warmer summer months. More than 80% of the deaths attributable to the bacteria since 1978 have occurred in the six-month period ending in October, and more than 50% have occurred in the three-month period of August through October. No deaths attributable to *V. vulnificus* contamination in raw oysters have been reported during the first three months of the year (D. Park, pers. comm.).

California, in response to eight confirmed *V. vulnificus*–related cases between 1985 and 1990, initiated a program in March 1991 which required all restaurants and stores selling Gulf oysters to notify potential customers that the "consumption of raw oysters can cause illness and death among people with liver disease, chronic illness, or weakened immune systems" (Liddle 1991). California's mandatory warning received extensive press in local papers (and the trade literature) throughout the country, including the Gulf. Furthermore, about the time that California mandated warning labels, many of the Louisiana dealers began to voluntarily place warning labels on products sold in local markets (the warning label has since become mandatory in Louisiana as well as in some other Gulf states).

One can hypothesize that state actions (i.e., mandatory warning labels) and the associated media attention, to the extent that they increased consumer awareness of the health risks attached to the consumption of raw Gulf oysters, have resulted in a change in consumer preference (i.e., a reduction in demand) for Gulf oysters, particularly the raw product. One can further hypothesize that consumer preference (demand) for closely related substitutes that were not the subject of warning labels and media attention, such as oysters produced in the Chesapeake, may have been altered as a result of the increased information attached to the Gulf product.

Literature pertaining to consumer behavior with respect to food-borne contamination events was reviewed by Strand (1999), who reached the following generalizations concerning formation of perceptions by consumers from information presented to them. First, the information, which is subjectively evaluated with the process not being easily described, is critical to perception formation. Uncertainty contained in the information can also be critical in perception formation. Finally, the credibility of the information depends on the source of the information.

The formation of perceptions (or changes) can, in turn, alter consumer choice. With respect to changes in consumer choice, Strand (1999) first concluded that consumers react to negative news by reducing demand for the product and/or by taking defensive actions to lower the level of health risk. The author also concluded that as a result of uncertainty (e.g., uncertainty of the marketing channels through which they obtain their consumables), consumer choice could be altered (i.e., a reduction in demand) even though there is no scientifically supported risk to them from their normal consumption. According to Strand, there is evidence to suggest that consumers avoid uncontaminated seafood after news of contamination incidents, presumably due to lack of information. Finally, Strand suggests that changes in consumer choice (demand) for products containing persistent toxic compounds (like DDT) appear to be a reaction to cumulative news. Although the effects of this news may decay over time, the decay will be slow.

The synthesis provided by Strand (1999) yields several insights relevant to analysis of potential change in oyster demand as a result of warning labels and negative publicity. First, uncertainty is likely to be a major factor. The uncertainty is inherent in both the information presented to the consumer as well as in consumers themselves as to whether they possess the health characteristics (i.e., liver disease, chronic illness, or a weakened immune system)

*Corresponding author. E-mail: walterk@lsu.edu

that would make the consumption of raw oysters "risky." Second, one could argue that the change in demand for Gulf oysters is analogous to Strand's discussion regarding changes in demand for food products containing persistent toxic compounds. Specifically, whereas *V. vulnificus* is not a toxic compound, like a toxic compound it is persistent in nature and continues to receive press several years after initiation of warning labels. Finally, based on Strand's review, the inability of the "average" consumer to differentiate the Gulf product from oysters harvested in other regions of the United States, particularly the Chesapeake (the other historically major producing region of the species *Crassostrea virginica*) suggests that media attention associated with the Gulf product may have adversely influenced demand for oysters harvested from outside the Gulf.

The primary objective of this paper is to determine the extent to which increased information (warning labels and publicity) has affected the demand for Gulf oysters, the subject of the information, and the demand for a closely defined substitute that is not the subject of the information. Given its close relation to the Gulf product, the Chesapeake product was selected as the substitute product to examine. An ancillary objective is to measure the impact of changes in other relevant variables (e.g., landings and income) on the demand for oysters harvested from the Gulf and Chesapeake.

MODEL SPECIFICATION

Gulf Demand Model

For purposes of analysis, the demand for Gulf oysters is specified as

$$\begin{aligned} PG_t = {} & \beta_0 + \beta_1 QG_t + \beta_2 INC_t + \beta_3 VUL_t + \beta_4 SEAS_t \\ & + \beta_5 (SEAS^* VUL)_t + \beta_6 (QG^* SEAS)_t + \beta_7 LATX_t \\ & + \beta_8 LPG_t + \epsilon_t \end{aligned} \quad (1)$$

where PG_t denotes the deflated Gulf oyster price in quarter t expressed in dollars per pound of meats (1982–1984 Consumer Price Index equals base); QG_t denotes the Gulf oyster harvest in quarter t expressed in millions of pounds of meats; INC_t denotes the U.S. real disposable income in quarter t expressed in billions of dollars; VUL_t is a binary variable used to capture the expected change in demand associated with warning labels and associated media attention (equal to 0 before 1991 and 1 thereafter); $SEAS_t$ is a binary variable used to capture seasonality in the demand for Gulf oysters (equal to 0 for the months April through September, i.e., the 2nd and 3rd quarters, and 1 for all other months, i.e., the 1st and 4th quarters); $LATX_t$ denotes the combined Louisiana and Texas share of Gulf harvest in quarter t; LPG_t denotes the deflated Gulf price lagged one quarter; and ϵ_t denotes the error term. Parameters to be estimated range from β_0 to β_8.

The price-dependent specification of equation 1 reflects the fact that production in the Gulf tends to be primarily determined by the availability of oysters, which, in turn, is largely dictated by environmental influences. This would suggest that price would be more responsive to changes in quantity than vice versa. From a theoretical perspective, one would anticipate a negative price response to a change in Gulf harvest (QG_t), i.e., $\partial PG_t / \partial QG_t < 0$. As specified, furthermore, the response in price to a change in the quantity harvested is permitted to vary by season. In the 2nd and 3rd quarters, defined for purposes of this study as the summer months, the impact of a one-million-pound change in QG_t is equal to β_1. In the 1st and 4th quarters, the impact is equal to $\beta_1 + \beta_6$.

Assuming oysters to be a normal good, price is anticipated to respond positively to increases in real disposable income (INC_t). The variable VUL_t, as noted, was included to capture any decrease in demand associated with increased information (i.e., warning labels and media), and as such, the parameter β_3 is hypothesized to be negative. Because the incidence of *V. vulnificus* is temperature dependent and is higher in the warmer months of the year, it is further hypothesized that the impact of VUL_t may vary by season with the impact on demand being greater in the summer months. Therefore, an interaction term between $SEAS_t$ and VUL_t is included in equation 1. In the colder months, i.e., the 1st and 4th quarters of the year, which for purposes of this study are defined as the winter months, the impact of VUL_t on dockside price (PG_t) is equal to $\beta_3 + \beta_5$. In the summer months, i.e., the 2nd and 3rd quarters, the impact of VUL_t on dockside price is equal to β_3. Given that the impacts of VUL_t on PG_t are anticipated to be higher when temperatures are warmer, one would anticipate that β_5 is positive, implying that the absolute value of β_3 exceeds the absolute value of $\beta_3 + \beta_5$.

The variable $SEAS_t$, as previously noted, was included in the analysis to capture the hypothesized seasonality component in Gulf oyster demand. Although the adage "don't eat oysters in any month without an 'R' " may have little validity, particularly since refrigeration of the oyster product became the norm, some adages tend to endure the test of time, and, though not documented, it is thought that demand for oysters is lower in the warmer months of the year, *ceteris paribus*. Furthermore, as noted, demand in the summer months since the introduction of warning labels is anticipated to be below that of the preceding period. Differentiating equation 1 with respect to $SEAS_t$ (i.e., $\partial PG_t / \partial SEAS_t$) yields $\beta_4 + \beta_5 VUL_t + \beta_6 QG_t$. This would suggest that the term $\beta_4 + \beta_6 QG_t$, i.e., the impact of seasonality before increased information, is less than zero, and furthermore, that the impact of seasonality after the initiation of warning labels ($\beta_4 + \beta_5 VUL_t + \beta_6 QG_t$) exceeds that before the increased information.

Based on examination of reported dockside oyster prices by state (National Marine Fisheries Service 2000), there appears to be a premium attached to the price of oysters harvested in Louisiana and Texas (these two states represent the majority of Gulf production), perhaps due to a larger average size. Hence, one would expect that the average Gulf price is positively related to the share of production derived from these two states. The variable $LATX_t$ is included in equation 1 to capture the price effect associated with the apparent product heterogeneity.

The variable LPG_t is included in the Gulf dockside price model (equation 1) in an effort to capture any inertia in the change in dockside price to changes in exogenous variables. The value of β_8 is expected to fall between 0 and 1, with a value approaching 0 indicating instantaneous adjustment in price to changes in the value of exogenous variables whereas a value approaching 1 suggests a high degree of inertia.

Finally, substitute products are often entered as exogenous variables in demand models of this nature. One would hypothesize that oysters produced in other regions of the country would constitute the closest substitutes for Gulf oysters. Initial inclusion of Chesapeake harvest in the Gulf demand equation did not prove successful; hence, it was not included in the final version of the model. This finding is consistent with other information presented by Diop and Keithly (2000).

Chesapeake Demand Model

Corresponding to the demand equation for the Gulf oysters (equation 1) is a demand equation for the Chesapeake oysters specified as

$$PC_t = \alpha_0 + \alpha_1 QG_t + \alpha_2 QC_t + \alpha_3 INC_t + \alpha_4 VUL_t + \alpha_5 SEAS_t + \alpha_6 (SEAS^* VUL)_t + \alpha_7 (QC^* SEAS)_t + \alpha_8 LPC_t + \alpha_9 (QG^* VUL)_t + \alpha_{10} PFI_t + \xi_t \quad (2)$$

where PC_t denotes the deflated Chesapeake dockside oyster price in quarter t expressed in dollars per pound of meats (1982-1984 Consumer Price Index equals base); QC_t denotes the harvest of Chesapeake oysters in quarter t expressed in millions of pounds of meats; LPC_t denotes the deflated Chesapeake price lagged one quarter; PFI_t is a binary variable used to capture the incidence of *Pfiesteria* in the Chesapeake, which may have influenced the demand for Chesapeake product (equal to zero before the third quarter of 1997 and one thereafter); ξ_t represents the error term in quarter t; and α_0 through α_{10} are the parameters to be estimated. For reasons analogous to those given for the Gulf, the Chesapeake demand equation is specified as price dependent.

As with the Gulf demand model, one would expect the Chesapeake dockside price to be negatively related to own landings (i.e., $\partial PC_t/\partial QC_t < 0$) and the landings of the Gulf substitute product (i.e., $\partial PC_t/\partial QG_t < 0$). As specified, the impact of Gulf production on the Chesapeake dockside price is permitted to vary after the increased information attached to the Gulf product. As discussed in greater detail below, certain restrictions were imposed on the Chesapeake demand model (equation 2) so that the Gulf production had no impact on the Chesapeake price after 1990.

The impact of Gulf product warning labels and the associated media attention on the demand for the Chesapeake product is, *a priori*, uncertain. If consumers have perfect knowledge and act rationally, then one would hypothesize that warning labels and media associated with the Gulf raw product should lead to an increase in demand for the Chesapeake product, *ceteris paribus*. Conversely, if consumers have less than perfect information or do not act rationally, one could hypothesize that the Chesapeake price has been negatively affected by actions taken with respect to the Gulf product. Differentiating equation 2 with respect to VUL_t (i.e., $\partial PC_t/\partial VUL_t$) yields $\alpha_4 + \alpha_6 SEAS_t + \alpha_9 QG_t$. If negative, one would conclude that the Chesapeake price has been negatively affected from the increased information attached to the Gulf product. Although the direction and degree of impact is *a priori* uncertain, Strand's (1999) synthesis suggests that it is likely to be negative.

DATA AND ESTIMATION ISSUES

Data Issues

The Gulf dockside demand model (equation 1) and corresponding Chesapeake demand model (equation 2), developed and specified in the previous section, were estimated based on quarterly data covering the 1981–1997 period. All landings and price data were derived from unpublished data provided by the National Marine Fisheries Service. Some summary statistics, relevant to quantity and price variables included in the respective models, are presented in Table 1.

The deflated Gulf oyster price averaged $1.64 per pound during the 1981–1997 period but only $1.33 per pound since 1991. This is a reduction of almost 30% from the average reported price of $1.85 during 1981–1990. The quantity harvested averaged 5.2 million pounds per quarter during the period of analysis, with the pre-1991 quarterly production (5.4 million pounds) averaging approximately 10% more than the post-1990 production (4.9 million pounds). In general, little price variation was evident during the 1981–1997 period when examined on a seasonal basis even though production during the winter season, which averaged 6.1 million pounds per quarter, exceeded the production during the summer season, which averaged 4.3 million pounds per quarter, by approximately 40%. For the 1991–1997 period, winter season production averaged 5.7 million pounds per quarter compared with 4.2 million pounds per quarter in the summer season.

The deflated Chesapeake price averaged $1.95 per pound during 1981–1997 period based on average quarterly production of 1.8 million pounds (Table 1). Before 1991, the deflated Chesapeake price averaged $1.88 per pound, or approximately 2% above that reported in the Gulf, based on average quarterly production of 2.8 million pounds. After 1990, the quarterly deflated Chesapeake

TABLE 1.

Summary statistics pertaining to Gulf of Mexico and Chesapeake Bay oyster demand models.

	Overall Mean	Winter Mean	Summer Mean
1981–1997			
PG ($/lb)	$1.64 (0.51)[a]	$1.61 (0.52)	$1.66 (0.50)
PC ($/lb)	$ 1.95 (0.41)	$ 2.07 (0.38)	$ 1.82 (0.40)
QG (Mill lbs)	5.20 (1.91)	6.11 (2.08)	4.28 (1.17)
QC (Mill lbs)	1.82 (2.38)	3.06 (2.82)	0.58 (0.65)
1981–1990			
PG ($/lb)	$ 1.85 (0.51)	$ 1.82 (0.54)	$ 1.88 (0.49)
PC ($/lb)	$ 1.88 (0.49)	$ 2.08 (0.49)	$ 1.69 (0.43)
QG (Mill lbs)	5.38 (2.20)	6.40 (2.48)	4.36 (1.27)
QC (Mill lbs)	2.82 (2.67)	4.71 (2.61)	0.94 (0.63)
1991–1997			
PG ($/lb)	$ 1.33 (0.29)	$ 1.31 (0.28)	$ 1.34 (0.31)
PC ($/lb)	$ 2.03 (0.22)	$ 2.07 (0.15)	$ 2.00 (0.27)
QG (Mill lbs)	4.94 (1.40)	5.71 (1.31)	4.20 (1.05)
QC (Mill lbs)	0.39 (0.44)	0.70 (0.43)	0.07 (0.04)

[a] Standards errors of means are given in parentheses. PG and PC are respectively deflated Gulf of Mexico and Chesapeake oyster prices in quarter t. QG and QC are respectively the harvest of Gulf of Mexico and Chesapeake oysters in quarter t.

price averaged $2.03 per pound, based on quarterly production of approximately 390,000 pounds. Overall, the deflated Chesapeake price during 1991–1997 exceeded the Gulf deflated price for the same period by approximately 20%.

Estimation Issues

Three estimation issues pertinent to the current analysis—the treatment of lagged dependent variables in the analysis, the use of prior restrictions in the estimation process, and contemporaneous correlation of the error terms—are briefly reviewed below.

The Use of Lagged Values

The lagged Gulf and Chesapeake dockside prices (LPG_t and LPC_t, respectively), as noted, were included in the analysis based on the premise that the response in price to a change in an exogenous variable may not be completed during that quarter in which the change in the exogenous variable occurred, i.e., there exists some inertia in the change in price. Pindyck and Rubinfeld (1991) and Green (2000), who provided a complete discussion of the distributed lag models, derived the following infinite lag distribution that is relevant to the oyster model presented in the previous section:

$$Y_t = \alpha(1 - w) + wY_{t-1} + \beta X_t + (\varepsilon_t - w\varepsilon_{t-1}) \qquad (3)$$

where w is the lag weight assumed to be positive and declining geometrically. The implications associated with equation 3 are twofold. First, all past values of the exogenous variable (X) are captured in the endogenous variable (Y) lagged one period with the impact of a change in X on Y decaying at a geometric rate over time. Second, lagging the dependent variable results in the introduction of serial correlation of the error term, assuming ε_t in equation 3 does not exhibit an autocorrelation pattern.

Several methods have been proposed for estimating the geometric lag structured model in the presence of serial correlation. The most popular technique, and the one that is used in the current analysis, is the instrumental variable approach whereby an estimate of the lagged dependent variable is generated by regressing its value against the lagged values of the exogenous variables in the model. Then the model is estimated using a maximum likelihood procedure, which corrects for serial correlation.

Given the structure of a geometric lag model, it is useful to identify both the mean lag as well as the long-run impact associated with a permanent change in the level of an exogenous variable. The mean lag, defined as the amount of time that expires before one-half of the impact on the dependent variable is recognized in association with a one-time change in an exogenous variable, is equal to $w/(1 - w)$. In our case, w is the estimate associated with the Gulf or Chesapeake dockside prices lagged one period (i.e., β_8 and α_8, respectively). The long-run response to a change in an exogenous variable is equal to $\beta/(1 - w)$. Hence, as the value for w increases ($0 < w < 1$), the greater will be the amount of time, which expires before the full impact of a one-time change in an exogenous variable is recognized.

As a concrete example, let us examine the impact of a change in the dockside demand for Gulf and Chesapeake oysters in relation to a change in real disposable income (INC_t). Specifically, the immediate impact of a one-billion-dollar change in income on the dockside demand for Gulf oysters is equal to the parameter estimate β_2 (see equation 1), whereas an equivalent income change immediately affects the dockside demand for Chesapeake oysters by α_3 (see equation 2). However, the full impact of a change in income in the current time period (i.e., quarter t) may not be realized in the current period due to inertia in consumers varying their spending patterns (i.e., it may take several quarters for consumers to fully adjust their spending patterns as a result of a current change in income). With respect to the Gulf, the long-run change in demand in response to a one-billion-dollar change in income in the current period is equal to $\beta_2/(1 - \beta_8)$. For the Chesapeake, the long-run response is equal to $\alpha_3/(1 - \alpha_8)$. It can be easily demonstrated that as β_8 and α_8 approach zero, the long-run response to a change in income will approach the immediate response.

Prior Restrictions

Cointegration and vector autoregression analysis conducted by Diop and Keithly (2000) provided strong evidence that the Gulf market strongly influenced the Chesapeake market before 1991 (measured via the Chesapeake dockside price). After 1990, however, the Gulf market had little or no influence on the Chesapeake market, i.e., the markets became separate. Based on these findings, the parameters α_1 and α_6 were restricted to equal one another but be of opposite sign. Imposition of this restriction results in changes in Gulf production after 1990 having no impact on the Chesapeake dockside price. This is justified given the apparent separation of the two markets after institution of warning labels and the negative publicity associated with the Gulf product.

Seemingly Unrelated Regression (SUR)

The dockside oyster demand equations for the Gulf and the Chesapeake bear a close conceptual relationship with each other. Hence, one would expect there to be a correlation in the error terms between the two equations. As such, SUR was used to increase efficiency of the estimates. The analysis was conducted using PROC MODEL of the SAS/ETS Software (SAS Institute Inc. 1993).

EMPIRICAL RESULTS AND DISCUSSION

A summary of the regression results associated with the estimated Gulf and Chesapeake dockside demand models is presented in Table 2.

Gulf Demand Model

The estimated parameters in general agreed with prior expectations, and, with few exceptions, all estimated parameters were significant at the 90% confidence level. The estimated model explained approximately 91% of the variation in the dependent variable (Table 2).

To examine the impact of a change in harvest on the deflated dockside price, differentiate equation 1 with respect to QG_t, which, for the parameter estimates given in Table 2, yields

$$\partial PG_t/\partial QG_t = -0.1198 + 0.0591SEAS_t \qquad (4)$$

This suggests that a one-million-pound increase (decrease) in summer harvest results in an immediate $0.1198 decrease (increase) in the deflated Gulf dockside oyster price, which, when converted to 1997 dollars, is equivalent to a $0.197 decrease (increase). An equivalent change in the winter harvest, by comparison, results in

TABLE 2.

Estimated parameters and standard errors associated with Gulf and Chesapeake oyster demand models. Asterisk indicates parameter estimates significant at the $\alpha = 0.10$ level.

an immediate inverse price response of only $0.0607 per pound ($0.097 in 1997 dollars), or approximately one-half of that estimated for the summer season. The short-run price flexibility of demand with respect to harvest, which measures the change in price to a 1% change in harvest, was found to equal −0.309 in the summer season compared with −0.230 in the winter season. Hence, a 10% increase in the summer harvest is expected to result in an immediate reduction in the dockside price of 3.09%, whereas an equivalent increase in the winter harvest results in a 2.30% reduction in price. These figures suggest that the immediate price response to a change in harvest is relatively inflexible.

The structure of the model makes it important to differentiate an immediate impact from the long-run impact. In the long-run, a one-million-pound increase (decrease) in summer harvest was found to result in a $0.272 decrease (increase) in the deflated Gulf of Mexico dockside price ($0.436 in 1997 dollars), whereas a one-million-pound increase (decrease) in the winter harvest was estimated to result in a price decrease (increase) of $0.138 per pound ($0.221 in 1997 dollars). The mean lag length is equal to approximately 1.25 periods [i.e., 0.560/(1 − 0.560)], implying that one-half of a permanent change in landings in quarter t will be felt within the initial 1.25 quarters. The long-run price flexibility with respect to summer harvest was estimated to equal −0.702 compared with −0.523 with respect to winter harvest. Hence, the price response to harvest is inflexible even in the long run, which implies that increasing harvest will result in an increase in revenues to the fishermen.

The increased risk information provided since 1991 was found to significantly impact the Gulf oyster dockside demand in a negative manner, with the degree of the impact depending on season. To examine the impact, differentiate equation 1 with respect to VUL_t, which, for the parameter estimates given in Table 2, yields

$$\partial PG_t/\partial VUL_t = -0.5367 + 0.1406SEAS_t \qquad (5)$$

Warning labels and associated media attention resulted in an estimated reduction in the summer Gulf dockside price of $0.5367 per pound ($0.859 per pound in 1997 dollars) since 1991 compared with a reduction in the deflated winter price of $0.3961 per pound ($0.634 per pound in 1997 dollars). These reductions, however, reflect only the initial effect of the warning labels and media attention by season. The fact that the estimate of β_8, equal to 0.560, falls between 0 and 1 implies that as one moves further away from the date that warning labels were initially mandated, the greater the absolute value of the magnitude of the policy variable. In the long run, the impact of warning labels was estimated to result in a summertime reduction in the demand for Gulf oysters equivalent to $1.22 per pound ($1.95 per pound in 1997 dollars) and a wintertime reduction in demand equal to $0.901 per pound ($1.44 in 1997 dollars). The actual summer price in 1997 equaled $2.16 whereas the actual winter price equaled $2.22, suggesting that the summer price was reduced by nearly one-half as a result of the warning labels and media attention whereas the winter price was reduced by approximately 40%.

One could hypothesize that the impact of warning labels and the associated media attention decays at some rate with the passage of time as consumers either forget about the negative publicity or overcome initial fears. To examine whether this was the case, the analysis was also conducted for the 1981–1995 period. In general, the parameter estimates varied only marginally, suggesting that the decay in the initial impact is, at most, minor. This finding may reflect the fact that warning labels are permanent in nature; hence, the information attached to these warning labels continuously reinforces consumer perception that the consumption of raw oysters is "risky."

Differentiating equation 1 with respect to $SEAS_t$ yields the following equation based on the parameter estimates given in Table 2:

$$\partial PG_t/\partial SEAS_t = -0.3852 + 0.1406VUL_t + 0.0591QG_t \qquad (6)$$

The result of substituting the average pre-1991 winter harvest (i.e., 6.4 million pounds) into equation 6 suggests almost no consumer demand differential between winter and summer Gulf oyster

demand before the institution of warning labels and media attention, *ceteris paribus*. As indicated in Table 1, the observed summer price exceeded the winter price by $0.05 per pound before 1991. Given the results of the current analysis, it appears that the higher observed summer price reflects a lower level of production in the summer season. After 1991, in association with the mandatory warning labels and media attention, the difference in demand between the winter season and the summer season resulted in an expected short-run price differential of approximately $0.075 per pound ($0.12 per pound in 1997 dollars). In the long run, the price differential increases to $0.151 ($0.24 per pound in 1997 dollars).

Income, as indicated in Table 2, was found to significantly influence the Gulf oyster dockside demand with a $100 billion-dollar increase in real disposable income resulting in an immediate $0.033 increase in price and a $0.075 increase in price in the long run. The estimated long-run price flexibility with respect to income equaled 1.42, suggesting that a 1% increase in real disposable income results in a price increase in excess of 1% in the long run, *ceteris paribus*.

Chesapeake Demand Model

As with the Gulf demand model, the Chesapeake demand model appears to perform adequately based on the expected signs and statistical significance associated with most variables included in the equation. The adjusted R^2 associated with the Chesapeake model equaled 0.67 (Table 2).

For the parameter estimates in Table 2, differentiating equation 2 with respect to a change in QC_t yields

$$\partial PC_t/\partial QC_t = -0.2075 + 0.1626SEAS_t \quad (7)$$

It can therefore be concluded that a one-million-pound increase (decrease) in the Chesapeake summer harvest results in an immediate $0.2075 decrease (increase) in the deflated Chesapeake price ($0.332 in 1997 dollars) whereas a similar increase (decrease) in the Chesapeake winter harvest results in an immediate $0.0449 decrease (increase) in the deflated price ($0.072 in 1997 dollars). The long-run impact of a one-million-pound increase (decrease) in the Chesapeake summer harvest was found to result in a $0.323 decrease (increase) in Chesapeake price, which is considerably greater than the long-run impact of a similar change in the winter harvest ($0.0699, or $0.112 in 1997 dollars). The short-run price flexibility of the summer Chesapeake price with respect to own landings was found to equal 0.066 (0.10 long-run price flexibility), which is identical to that estimated with respect to the winter harvest.

Differentiating equation 2 with respect to a change in Gulf quantity yields

$$\partial PC_t/\partial QG_t = -0.1024 + 0.1024VUL_t \quad (8)$$

Before 1991, therefore, one would expect the deflated Chesapeake price to immediately decrease (increase) by $0.1024 ($0.164 in 1997 dollars) in response to a one-million-pound increase (decrease) in Gulf production. The long-run response would be $0.159. Given the restriction imposed on the Chesapeake demand model (based on separate markets after 1990), changes in Gulf landings after 1990 had no impact on the Chesapeake dockside price.

Changes in the deflated Chesapeake dockside price in response to the mandated warning labels on the Gulf product (and associated negative publicity) can be evaluated by differentiating equation 2 with respect to VUL_t, which yields

$$\partial PC_t/\partial VUL_t = -0.3600 - 0.5673SEAS_t + 0.1024QG_t \quad (9)$$

Based on the mean level of summer Gulf landings during 1991–1997 (4.2 million pounds), the impact of warning labels and media attention attached to the Gulf product was found to result in an immediate price increase in the deflated Chesapeake dockside summer price equal to $0.0496 per pound ($0.079 in 1997 dollars). The Chesapeake winter price, however, was estimated to decline by $0.374 per pound ($0.60 in 1997 dollars) as a result of warning labels and media attention attached to the Gulf product. Overall, one can conclude that the increased summer price reflects the fact that, given the structure of the model, the Gulf product does not compete with the Chesapeake product after 1990; hence, the lack of the substitute product for the Chesapeake product in the summer months results in an overall increase in the Chesapeake price. The long-run impact of warning labels and media attention on the Chesapeake dockside equaled $0.077 in the summer months ($0.124 in 1997 dollars) and resulted in a reduction in the "winter" price equal to $0.564 per pound.

Season ($SEAS_t$) was found to strongly influence demand for the Chesapeake product. Based on the mean level of Chesapeake winter production before 1991 (4.71 million pounds), the results suggest that higher demand in the winter months resulted in a price increase of $1.35 per pound ($2.16 in 1997 dollars) when compared with the summer price (before 1991). The price differential narrowed to only $0.16 per pound after the 1991 events in the Gulf.

The parameter estimate associated with disposable income in the Chesapeake equation was found to be negative but statistically insignificant. The unexpected sign associated with INC_t may reflect the strong influence that the Gulf product has on the Chesapeake price.

The parameter estimate associated with pfisteria (PFI_t) was found to be negative but statistically insignificant in determining the demand for the Chesapeake oyster (Table 2). Because PFI_t was observed in the Chesapeake for a very short period of time, this may explain why it was not a factor in explaining the changes in Chesapeake oyster demand.

Finally, the mean lag length in the Chesapeake market was found to equal 0.55 periods [i.e., 0.3577/(1 − 0.3577)], implying that one-half of a permanent change in Chesapeake landings in quarter t will be felt within 0.55 periods of the first quarter. This implies that the lagged Chesapeake price plays the role of a propagation mechanism that carries over the remainder of the change from one quarter to the next.

Revenue Implications

The results presented here can be used to assess the welfare implications associated with increased consumer awareness associated with the consumption of raw oysters. For example, since 1991, the demand for Gulf oysters has shifted downward, leading to lower harvested quantities and prices. The estimated dockside equations were used to quantify the welfare effects of *V. vulnificus* on the oyster industry. Quarterly predictions of prices with increased consumer awareness were compared with simulated prices in the absence of warning labels and media attention. For the period covering 1991 through 1997, the difference in prices multiplied by the corresponding quantities represented the overall loss in revenue to oyster harvesters. The overall industry loss in revenue (in 1997 dollars) due to increased consumer information amounted to $16.4 million, with the Gulf producers incurring

about 95% of the losses and the Chesapeake producers the remaining 5%. The $7.82 million loss for the Gulf producers during the summer months represented 50% of the overall $15.6 million loss for that region. The Gulf harvesting sector bore most of the losses because it is the primary oyster-producing region in the United States.

NATIONAL INDICATOR STUDY: IS AN INTERNATIONAL APPROACH FEASIBLE?

DOROTHY L. LEONARD
776 Rolling View Drive, Annapolis, Maryland 21401

ABSTRACT The National Indicator Study (NIS) was established in the United States in 1989 with the purpose of improving the shellfish classification systems for molluscan shellfish growing waters using the latest technological advances in microbiological and epidemiological methods. A total of ten methods development projects were completed, eight addressing indicators of pathogens associated with molluscan shellfish and two with direct detection of specific viral pathogens, Norwalk and hepatitis A. In 1993, the results of all ten projects were submitted to peer review by a panel of scientists. Two of these candidate indicators were selected for further development: particulate-bound secretory immunoglobulin (sIgA) and the male-specific coliphage. This paper reviews the funded projects, the Literature Review and Manual of Methods that were funded by the study, and raises the question: should an international indicator study be pursued, by whom, and through what sources of funding? Unfortunately, the NIS was discontinued in 1994 before it achieved any quantitative information on the efficacy of these new or existing indicator methods as they might relate to the improvement of water classification procedures or health risks to consumers.

KEY WORDS: National Indicator Study, molluscan shellfish, National Shellfish Sanitation Program, Interstate Shellfish Sanitation Conference

INTRODUCTION

The current system used to determine the suitability of molluscan shellfish (oyster, clam, and mussel) harvest waters to produce a raw product safe for human consumption originated in 1925. The management system was developed by the U.S. Public Health Service working cooperatively with state health departments to control typhoid and cholera outbreaks that were associated with the consumption of raw shellfish. Because the actual control of molluscan shellfish in interstate transport is the responsibility of the states, they, in turn, formed the Interstate Shellfish Sanitation Conference (ISSC). The ISSC, in cooperation with the U.S. Food and Drug Administration, developed the National Shellfish Sanitation Program (NSSP), which provides criteria for the protection of harvest waters, harvesting, transport, and processing of shellfish (ISSC et al. 1999).

At the harvest level, the NSSP provides guidance for states conducting sanitary surveys in the harvest areas. These sanitary surveys are used to assess water quality and determine the suitability of shellfish for human consumption. The shoreline survey and bacteriological examination of molluscan shellfish waters for indicator organisms are routinely performed in harvest areas. However, when harvest areas are subject to intermittent pollution events, states must exercise more intensive monitoring after the event to ensure that the shellfish are cleansed of indicator organisms. Some shellfish waters are used as sources for natural or mechanically controlled cleansing of shellfish (relay or depuration operations, respectively).

The shoreline survey is the most important step in the approval of waters for direct harvest. The survey involves (1) physical examination of properties and facilities that may contribute pollution of public health significance; (2) review of relevant discharge permits; (3) use of dye studies, dispersion models, and other hydrographic techniques to evaluate the dispersion and dilution of point source effluent; (4) evaluation of treatment reliability at major waste water treatment plants; (5) evaluation of agricultural best management practices (BMPs) for animal waste containment and similar activities directed at pollution identification and control. The successful completion of shoreline surveys often requires the skills, resources, and cooperation of several state and local agencies. These surveys provide the framework for assessing the significance of indicator organisms found in bacteriological examination of shellfish waters and meats.

The bacteriological examination of shellfish harvest waters is used to verify information obtained from shoreline surveys. Elevated levels of indicator organisms in approved harvest areas indicate a need for shoreline survey reexamination. Between shoreline surveys, monitoring of indicator organisms can confirm that no significant new sources of human sewage were introduced into a harvest area. The NSSP states that the determination of the acceptability of a harvest area should be based on both the shoreline survey and water quality sampling information.

During recent years the suitability and credibility of the existing coliform indicator have become increasingly questionable, particularly with respect to the transmission of viral illness. Consumers, scientists, state and federal regulators, and industry representatives are questioning whether the current indicators and the existing numeric criteria adequately predict the risk of illness transmission to consumers (Hackney 1993b).

DO WE NEED AN INTERNATIONAL INDICATOR STUDY?

In all countries where raw molluscan shellfish products are commercially available, the public expects those products to be safe for human consumption. Public health agencies and resource agencies within shellfish-producing countries are charged with determining the acceptability of shellfish harvest waters as safe sources of food. These agencies need better analytical tools and microbial standards to improve their performance in the evaluation of the safety of shellfish harvest waters. Currently, there are different indicators and protocols used throughout the shellfish-producing world, and these are sometimes perceived as trade barriers. Of concern to the U.S. industry is the lack of a level playing field to facilitate shellfish trade (Leonard 1992b). Also, the molluscan shellfish industry needs assurance that it is marketing a safe product from safe waters. Better indicators of the safety of molluscan shellfish for consumption will help provide that assurance.

Uncertainties related to the current indicators have also led to concerns that their use may result in harvesting restrictions in areas where human health risk is minimal. As a result, recreational and commercial harvesters, as well as some agency regulators, believe

E-mail: msmussel@toad.net

the public may be unjustly deprived of resource use. This belief is particularly strong with respect to areas affected primarily by runoff from fields, forests, and marshes where there is little or no human habitation. In other situations, it is believed that impacts from human sources that may cause a human health risk remain undetected because of the inadequacies of the current coliform indicator (Hackney 1993b).

The question arises as to why the search continues for new indicators. Why not concentrate on testing for the pathogens of concern? The reasons for not pursuing specific pathogen isolation are many. First, specific pathogen isolation is not cost effective. Methodologies are cumbersome, time consuming, and expensive. Several of the important illnesses associated with shellfish consumption are diagnosed by the symptoms the pathogen induces in people because no method exists for pathogen isolation. Secondly, pathogens occur in fewer numbers in fecal material than other microbial organisms, particularly in the combined sewage wastes from large populations. When the wastes are discharged into or near harvest waters and then diluted, the probability of capturing the pathogenic organisms in a small sample size diminishes rapidly.

Another complication in direct pathogen isolation is that pathogens are not evenly distributed in shellfish harvest waters. Failure to detect a pathogen in a specified volume of water (a sample) is not proof that the pathogen is absent in the larger water body from which the sample was taken. It only verifies that the pathogen was not detected in that set of samples. Furthermore, the presence or absence of a particular pathogen does not necessarily correlate with the presence or absence of another pathogen. The lack of this correlation among pathogens would require testing for all pathogens, a task that is not economically feasible.

In the United States, the coliform indicator has been fairly effective in predicting the presence of fecal-borne bacterial pathogens. However, in the last 30 years there have been increasing disease outbreaks from viral rather than bacteriological pathogens, and the coliform indicator may not be at all effective to determine absence/presence and concentration of viruses. In recent years, the ISSC has focused their efforts on reducing confirmed disease cases resulting from naturally occurring pathogens in estuarine waters such as *Vibrio vulnificus* and *Vibrio parahaemolyticus* and the impacts of harmful algal blooms. In these cases, the fecal coliform indicator cannot be used to determine pathogen or toxin levels.

THE NIS CHRONOLOGY

In the summer of 1987, a group of twenty scientists and managers met in Cocodrie, Louisiana to design a study that would result in improved risk management of the sale and consumption of raw molluscan shellfish. The incentive for this memorable meeting came from the Gulf oyster industry, which had lost confidence in the NSSP and felt an obligation to its consumers to better ensure the safety of its products. Conditions were a little rough at the unfinished facility of the Louisiana Universities Marine Consortium (LUMCON), but the study design group was so successful in developing a plan and cost estimates that they still form the core of the NIS. The purpose of the NIS was to improve existing classification systems for molluscan shellfish–growing waters using the latest technological advances in microbiological and epidemiological methods. The goal was a long-term research program to develop and evaluate the effectiveness of new indicators of health risk associated with consumption of raw molluscan shellfish.

The NIS was managed in cooperation with the ISSC and the LUMCON. The ISSC provided oversight and developed the goals and objectives of the study. The NIS Committee (NISC) of the ISSC was established in May 1991 under a Memorandum of Understanding between the National Marine Fisheries Service (NMFS) and the ISSC. The ISSC and LUMCON reached agreement in December 1991 whereby LUMCON would provide scientific management on behalf of the NISC. A contract between NOAA and LUMCON was executed in July 1992 to provide an appropriate funding mechanism to support LUMCON's activities, including subcontracted research.

With this administrative structure now in place, the NISC continued to follow a course of work in accordance with the original plans of the NIS, i.e., to develop and test new and improved methods for measuring human-specific indicators of fecal pollution in molluscan shellfish–growing waters. Methods development was considered the first phase of a much larger research program that would eventually be directed to quantitative assessment of the health risk to shellfish consumers. Consequently, LUMCON was requested to develop, via subcontract, improved procedures for measuring sewage-related microorganisms in shellfish meats. The research was halted in June 1994, following the announcement of the discontinuance of the NIS. The NISC met for the final time in February 1994, at which time its members were advised that no further funding would be made available to support the study and the NIS would be closed down within the current fiscal year.

RESEARCH RESULTS

A total of ten methods development projects were completed over the entire course of the NIS since its inception in 1989. Of these, eight dealt specifically with indirect indicators of pathogens associated with molluscan shellfish and two with direct detection of specific viral pathogens, Norwalk and hepatitis A.

The results of all 10 projects were subjected to peer review by an independent panel of scientists convened by the NISC in September 1993. The panel was charged with reviewing the research for technical merit and completeness of data, its applicability and utility, and its consistency with NIS objectives. The panel was also asked to offer recommendations on the NIS strategy, including additional research to identify, isolate, culture, and quantify indicator organisms.

The review panel concluded that, among the various indicator methods studied, two should be considered as candidates for further development as human-specific indicators of fecal contamination. The most promising candidate was found to be particulate-bound secretory immunoglobulin (sIgA), a chemical indicator that could be used to identify nonpoint sources of pollution, such as septic systems (human sIgA) and wildlife wastes (animal sIgA). The other strong candidate was male-specific coliphage, which can be serotyped to distinguish between human and animal sources of pollution. Specific recommendations of the review panel concerning these two methods and the other research approaches were summarized in a draft report prepared by the NISC in January 1994 (ISSC 1994).

NIS PRODUCTS

Hackney, C. R. and M. D. Pierson, editors (1994) *Environmental Indicators and Shellfish Safety*

An early objective of the NIS was to prepare a comprehensive literature review of environmental indicators and shellfish safety so as to provide a framework for evaluating the efficacy of current indicators and seeking ways to improve or replace them for use in the classification of molluscan shellfish growing waters. The review, titled *Environmental Indicators and Shellfish Safety*, was published in 1994 in book form. It is also available in electronic form upon request through the ISSC. The book begins with the history of shellfish safety. This chapter was written by the former head of the U.S. FDA's Shellfish Sanitation Branch and contains much information, before only available as FDA files. The second chapter is on microbial and chemical indicators of pollution. This is perhaps the most comprehensive chapter ever written on the subject. The author of this chapter, Howard Kator, has been the chairman of the ISSC microbiology committee for several years and has had considerable research experience on the relationship between environmental indicators and pathogens. The next four chapters examine shellfish safety with respect to enteric viruses and bacterial pathogens, and their relationship to environmental indicators. These chapters present characteristics of the organisms, their survival in the environment, the methodology to recover the organisms, and their relationship to environmental indicators and human illness. The next three chapters concentrate on the methodology, including rapid methods and the emerging methodology. The phenomenon of cell injury is reviewed along with viable but nonculturable cells. Following this section, the changes in indicator and pathogen populations during handling or storage of shellstock and during processing are reviewed. The last four chapters of the book review sanitary surveys of growing waters, depuration and relaying of molluscan shellfish using indicator information for managing risks, epidemiological studies, and statistical sampling of growing waters and shellfish meats.

Hackney, C. (1994) *Reported Human Illness from Consumption of Molluscan Shellfish in the United States from 1973–1990*

This report summarized data from the U.S. Centers for Disease Control (CDC) and the U.S. Food and Drug Administration's North East Technical Services Unit (NETSU) concerning reported human illness associated with the consumption of molluscan shellfish. The CDC database included the years 1973 to 1987, whereas the NETSU database included 1973 to 1990. The databases do not agree because of the different sources of information used to compile each. The CDC database is the annual summaries of outbreaks and cases reported by the states, one of three data sources for information from CDC. Other information sources include the Laboratory Surveillance System and the CDC publication *Mortality and Morbidity Weekly*. The Laboratory Surveillance System mostly targets specific organisms such as *Salmonella* spp. The CDC and NETSU databases also differ in the definition of shellfish. In the CDC database, shellfish is broadly defined, and includes crustaceans, bivalves, and univalves. In the NETSU database, shellfish is much more narrowly defined as bivalve mollusks. Also, the NETSU database is very specific as to shellfish species, illness, etc. Each case or outbreak is briefly described. The information given includes location of illness, location of harvesting state if known, the shellfish species, the bacterial or viral agent, the reference cited, and brief comments on the case.

The NETSU database is a summary of cases, not outbreaks. Information in this database comes from CDC, books, city and state health department files, news reports, and Public Health Service Regional files. Thus, the NETSU database is more complete but at the same time less precise. The NETSU data includes individual cases that were not reported as outbreaks. The CDC defines outbreak as two or more persons becoming ill after consuming a common food at the same time. Illness that only affects one individual will not be reported in the CDC database. For example, the NETSU database lists over one hundred thirty five cases of *Vibrio vulnificus*, but because this bacterium only affects individuals in high-risk categories, no outbreaks (two or more individuals having a similar illness after consuming the same food) have been reported. Thus, illnesses from this organism do not appear in the CDC database used for annual summaries.

The information in the tables is useful for estimating the risk from microbial contaminants. Most of the illness associated with molluscan shellfish has been associated with either enteric viruses or naturally occurring marine organisms of the family *Vibrionaceae*. Other microorganisms account for far fewer illnesses.

Hackney, C. (1993a) *The Molluscan Shellfish Industry*

The objective of this report was to provide an overview of the molluscan shellfish species that are harvested and the methods used to process the shellfish for market. The report is divided into two parts: shellfish species and processing.

Hackney, C. (1993b) *The Current Shellfish Indicator System: Opinion Survey of the Molluscan Shellfish Industry*

The purpose of this report was to determine what the molluscan shellfish industry believed about the current indicator system. Although 45 percent of the respondents believed that the current standards are too restrictive, 55 percent believed that the standards are not adequately protecting consumers. Only 27 percent believed that the current standards accurately reflect health hazards. Over-

all, the responses indicate that there are strong opinions on the standards and reservations about their effectiveness.

Kator, H., editor (1994) *Manual of Procedures for Analysis of Molluscan Shellfish and Growing Waters*

This manual, a compendium of existing methods, was developed to assist in the evaluation of shellfish and their growing waters. During the formulation of the strategy for the NIS, agreement on laboratory methods was determined to be a critical factor. The comparison and reliability of data gathered to identify, isolate, and enumerate both traditional and new indicators of public health risk associated with fecal contamination of molluscan shellfish harvest areas were believed to be highly dependent on the laboratory methods used and uniformity in the application of methods. Without reliable, comparable data, risk assessment across the field sites in the epidemiological investigation would not be possible. The purpose of this manual was to assemble under one cover a variety of methods for microbial indicators identified by early NIS committees and workshops as promising for additional study or for use in the NIS study. This compilation of methods was not intended to replace the highly detailed methodologies in the American Public Health Association, the Association of Analytical Chemists of the U.S., or the U.S. Food and Drug Administration manuals. The manual was more properly viewed as a compendium of many methods with potential application to the microbiological assessment of shellfish and their growing waters. Future manuals, which were not prepared because of termination of funding for the NIS, were envisioned as being considerably more detailed and containing those methods actually used in the NIS program.

Leonard, D., M. Broutman, and K. Caverly. (1988) *The National Collaborative Shellfish Pollution Indicator Site Selection* and Leonard, D., and E. Slaughter. (1990) *The National Collaborative Shellfish Pollution Indicator Site Selection: Phase II*

The third component of the NIS was an epidemiological study that was to evaluate the relationship between illness in volunteers ingesting raw shellfish in an intensively monitored and controlled situation, and the water quality in the harvest areas as measured by traditional and new indicators of fecal pollution. Recognizing the need to begin investigation and characterization of potential sites for the NIS, the program commissioned a review of available information in 1987 through 1988. Criteria for site selection were established. Recommendations were solicited from representatives of state and federal regulatory agencies and seafood harvesters and processors in five different regions of the United States. Preliminary selection of one hundred sites was made. This report describes the process used and lists, by region, the potential sites identified. The information contained in the 1988 report was reevaluated using a relational database program designed by EG&G Washington Analytical Services Center, Inc. and the National Oceanic and Atmospheric Administration. This approach reduced the number of sites for consideration to forty-six. The results of this analysis are contained in the report.

Leonard, D. (1992a) *Site Assessment Guidance Document*

The site assessment guidance document was written to facilitate the performance of site assessments at every site considered for inclusion in the NIS epidemiological phase. Ideally the work would be performed within the year preceding the beginning of controlled feeding studies. Although several subcontractors could be involved in a site assessment, all activities would be required to follow the procedural guidelines and quality assurance, as outlined in the manual. Data entry forms approved for the NIS were included in the appendices and would be required for all data collection and data submission. Whether data is entered into the computer by the on-site contractors or forwarded to the data management center for data entry, the formats used to receive the data would be those approved by the data management center. At the end of the site assessment process, the contractor was required to provide background information, hydrographic study results, and microbiological sampling results. Recommendations would then be made on sample site locations for use in the epidemiological phase.

Other NIS Products

The NISC issued a "white paper" on the National Indicator Study in June 1993. The report described the NIS approach to improving the water quality management system currently used to ensure the safety of raw molluscan shellfish. A summary of the three major components of the study, laboratory methods development and validation, field trial of methods at defined sampling sites, and a human feeding study to determine exposure–response relationships, was also provided in the report. Subsequently, in October 1993, a draft 5-year plan for the NIS was prepared by NOAA in cooperation with ISSC, NISC, and LUMCON. The plan elaborated on the white paper and included a final step to conduct a risk assessment and develop a risk management strategy. This long-range planning document was followed by the preparation of a Plan of Operations that was received and accepted in draft form by the NISC at its February 1994 meeting. All work on the planning documents was halted following the decision to discontinue the study.

IMPEDIMENTS TO COMPLETION

There are many reasons why the NIS was not completed as planned: political problems, issues with epidemiological studies, industry impacts and concerns and, the most critical, sufficient resources. Without a sufficient funding base, this scientifically based program could not be undertaken. In the initial scoping document prepared in Cocodrie in 1987, the team estimated that 25 million dollars would be sufficient and achievable with a special appropriation from Congress. Although Congress was supportive of the needs of the shellfish industry and the consumer public, they were not ready to commit to this figure. Thus, the funding was budgeted through NOAA in small amounts, sufficient to accomplish 10 research projects, but not sufficient to field test indicators and methods nor conduct a full-scale feeding study.

The political pressure to conduct a national-scale project to test indicators and develop new methodology came from the shellfish industry. Public officials, the scientific community, and consumer groups did not put their collective power behind the NIS, a move that might have guaranteed success. In fact, there was opposition in some organizations based on jealousies, fear of stepping into unknown territory, and unwillingness to change current systems. Politics within the scientific community created a barrier to full cooperation among the researchers. In order to ensure a successful project on an international level there will need to be full cooperation, trust, and transparency in most project-related activities.

The conduct of a full-scale feeding study is extremely complex

and requires the expertise of organizations and medical personnel who have successfully complied with all requirements in previous studies. Experimental subjects are well protected and often are well-paid volunteers. Follow-up can be lengthy, particularly in cases where a disease agent has been identified. However, as difficult and expensive as these studies may be, it is acknowledged that if we are to adopt a suite of indicators that are scientifically supported, the studies must be done.

The motivation to develop new indicators came from the shellfish industry. Their concerns were twofold; first, that shellfish-growing areas are closed based on a coliform indicator that is not indicative of human disease potential, and second, that conversely, some areas remain open to harvest although there may be pathogens of concern present in the shellfish. In the early 1990s, the industry had to change their focus from the NIS to illness and deaths occurring from *Vibrio vulnificus*, *Vibrio cholerae* non-01, and *Vibrio parahaemolyticus*. Even though the cases are few, the effects from *V. vulnificus* in immunocompromised consumers are often fatal. Under pressure from consumer groups and the press, the ISSC and shellfish industry have had to focus all possible resources on this issue.

U.S. EPA's BEACH Program

Within the United States as well as internationally, there are debates between agencies regarding the effectiveness of chosen indicators. For example, the U.S. EPA has been increasingly concerned with the public health risks of swimmers exposed to infectious diseases on our nation's beaches and the effectiveness of the indicators used to monitor swimmer safety. To counteract this problem, the EPA has established the Beaches Environmental Assessment Closure and Health (BEACH) Program. In 1986, the EPA issued a revision to its bacteriological ambient water quality criteria recommendations to include new indicator bacteria, *E. coli* and enterococci, which provide a better correlation with swimming-associated gastrointestinal illness than the previous criteria, fecal coliform bacteria. These revised criteria are useful to public health officials because they enable quantitative estimates of illness rates associated with swimming in polluted water. A new enterococci method is a revision of the EPA's previous method, used since 1985 in ambient water quality monitoring. It reduces analysis time to 24 hours and improves analytical quality. The method has been validated in single- and multi-laboratory studies and has undergone peer review.

IS AN INTERNATIONAL APPROACH FEASIBLE?

International Aspects

In the United States there are a number of federal agencies that are involved in the development and application of microbiological standards in food products including molluscan shellfish. These include the Food and Drug Administration, Department of Commerce, Department of Defense, Veterans Administration, Department of Agriculture, and Environmental Protection Agency. In addition, numerous state and municipal agencies and private firms are involved in application of these standards.

Much more complex is the array of international organizations with interests or roles in the discipline of microbiology in food regulatory systems. Among the fourteen identified organizations are FAO/WHO Codex Alimentarius Commission, European Economic Community(EEC), International Standards Organization, International Commission on Microbiological Specifications for Foods, Nordic Food Group, and the FAO/WHO-sponsored Expert Microbiological Consultations. In spite of the appearance of coordination, there is a mix of both microbiological and toxin standards applied worldwide (Leonard 1992b).

The major difference in microbiological standards used by the United States and other shellfish-producing countries is the application to waters rather than meats. Only the United States, Canada, and Chile classify shellfish-growing and -harvesting waters using the fecal coliform standard. On January 1, 1993, the EEC implemented health conditions for the production and placing in the market of live bivalve mollusks. Although there are some amendments, these standards have been adopted by all members. Chapter I of the Annex, Conditions for Production Areas, dictates how boundaries and classifications of production areas are determined. Despite these differences, the NSSP and EC Directive are based on the assumption that a relationship exists between sewage pollution of shellfish-growing areas and human disease.

Trade Issues

The United States has a bilateral agreement with Canada and FDA-approved programs in Chile, Korea, and New Zealand. However, trade between the United States and all other shellfish-producing countries requires certification by local authorities. This certification is based on an understanding or agreement that the standards in both countries are equivalent. Unfortunately, neither the industry nor the officials involved in the certifications feel confident that true equivalency exists. In fact, in some other situations, the U.S. industry believes that depuration or postharvest processing are unnecessary requirements although required of all imports to the receiving country.

Other issues shared by all shellfish-producing countries are risk assessment, management, and communication as well as HACCP and other inspection issues. These are areas in which we can work on a cooperative basis, focusing resources, exchanging ideas and technology, and building open communication and trust. If the guidelines and regulations are developed jointly, then the goals of transparency and equivalency are accomplished.

CONCLUSION

Based on discussions that took place at the International Conference on Molluscan Shellfish Safety at Southampton, New York, in June 2000, I believe it is not only feasible but also incumbent upon us to develop an International Working Group on Microbiological Standards and begin a process to develop better risk management tools. We are prepared to develop a web site based at the University of Florida that will open the doors to communication. The purpose of the site is to allow posting of new methods, findings, and shared ideas and concepts. It will also have the capability of conferencing and chat rooms. Rather than develop another layer of international bureaucracy, we will work scientist to scientist and manager to manager, involving the shellfish industry in our deliberations and information dissemination.

The extensive work that has been completed under the National Indicator Study will be available to everyone who can access a web site. In the interim, information can be accessed by calling the Interstate Shellfish Sanitation Conference at (803) 788-7559 or by accessing the web site at http://www.issc.org/issc/.

THE USE OF HIGH HYDROSTATIC PRESSURE TO SHUCK OYSTERS AND EXTEND SHELF-LIFE

HAIAN HE, ROGER M. ADAMS, DANIEL F. FARKAS, AND MICHAEL T. MORRISSEY
Oregon State University Seafood Laboratory, 2001 Marine Drive, Room 253, Astoria, Oregon 97103

ABSTRACT High hydrostatic pressure (HHP) was used for mechanically shucking oysters. Microbial, chemical and descriptive evaluations were performed over a 3–4 week period for HHP samples and controls. Results from this study demonstrated that HHP was effective in shucking oysters at 35,000 to 40,000 psi. Results showed that HHP treated oysters maintained higher pH than the control over the storage period. Moisture content of the control decreased about 3% while HHP treated samples increased 2%. Pressure treatment did not significantly inhibit lipase activity during the shelf-life study. It was observed that HHP had a significant effect on reducing initial microbial load by approximately 2 to 4 logs. Descriptive evaluation showed HHP treated oysters had better quality than that of control during the shelf-life period. HHP proved to be an effective method for shucking oysters and extending shelf-life.

KEY WORDS: hydrostatic pressure, shucking, extending shelf-life

INTRODUCTION

Oysters are filter feeders and contain a high level of microbial flora, which will cause eventual spoilage and may pose a threat to public health. There is an increasing concern with the safety of raw oyster consumption, but at the same time consumers demand remains high for oysters that retain the original nutrients, flavor and appearance. Consequently, high hydrostatic pressure (HHP) has become the newest and potentially most promising method to purify oysters. HHP is a 'heatless process,' which has an effect on microorganisms' survival and enzymatic activity in foods (Hoover et al. 1989). HHP induces a number of changes to morphology, biochemical reactions, genetic mechanisms and cell membranes and walls of microorganisms (Smelt 1998).

Previous work with HHP and shucked oysters has shown that this treatment is effective in reducing total bacterial load in shucked oysters (Shiu & Morrissey 1999). In addition, preliminary work with HHP and whole oysters indicated that the treatment could be used for mechanically shucking oysters. The high pressure appears to preferentially sever the adductor muscle from the shell without altering the appearance of the raw oyster. This combination of mechanical shucking and microbial reduction in oysters by HHP could dramatically change the traditional oyster processing operation. The objective of this study was to determine the optimum HHP conditions (pressure/time) for shucking the oysters and the effect of HHP on the microbial, biochemical and descriptive evaluation of oysters.

MATERIALS AND METHODS

Oyster Source

Live whole oysters and hand-shucked oyster meats used as controls were collected from a local oyster processor in Willapa Bay, WA, and transferred to the OSU Seafood Laboratory as soon as possible after harvest. Whole oysters were stored at 10°C during transportation, while shucked meats were stored at <4°C.

Pressure Treatment

Whole oysters were vacuum packed in a waterproofed bag and subjected to eight different pressure treatments: (a) Control samples—no treatment; (b) Pressure treatment 30,000 (30k) psi, 2 min; (c) 35k psi, 0 min; (d) 35k psi, 1 min; (e) 35k psi, 2 min; (f) 40k psi, 0 min; (g) 40k psi, 1 min; (h) 45k psi, 0 min. Samples were pressure treated in an isostatic pressure unit (Model IP-3-22-60, Autoclave Engineering, Inc.).

Sample Preparation

Shucked oysters, 4 from each treatment and controls, were packed with water into a 100 ml jar, 4 oysters per container. Before biochemical and microbial tests, oysters were aseptically transferred to a pre-sterilized blending jar. Samples were then homogenized for 3 s. Oysters used for sensory tests were directly transferred to petri dishes from jars.

Biochemical Tests

One gram of homogenized samples was diluted with distilled water (1:10) and tested for pH using a pH meter. Moisture content was determined by the oven drying method as described in AOAC (1984). Lipase activity was determined by the method based on detection of the fluorescence of 4-methylumbelliferone (4-MU) produced by enzymatic hydrolysis of substrates (Stead 1983).

Microbiological Tests

Aerobic plate counts (APC) were measured using petrifilm and all the plates were incubated at 25°C for 72 hours. Anaerobic plate counts (ANPC) were measured using the pour plate technique and were incubated in anaerobic chambers at 35°C for 48 hours.

Descriptive Tests

Descriptive tests were performed after HHP treatment by a trained panel using a freshness grade guide (developed at OSU Seafood Laboratory) determined over a three-week period. Quality Index Method (QIM) was used to predict shelf-life of all oyster samples (Bremner et al. 1985).

Statistical Analysis

Data were analyzed for significant differences using an analysis of variance (ANOVA). All statistical analysis was performed using STATGRAPHICS plus Version 3.1.

RESULTS AND DISCUSSION

Different HHP treatments had varied effects on degree of shucking, microbial counts and the descriptive evaluation of oysters' meat. HHP-shucking results showed that higher pressure and longer time caused optimum detaching of adductor muscle. The

minimum pressure/time parameters for approximately 90% success in oyster shucking (detachment of adductor muscle) was 35k psi for 2 min. All HHP treated samples maintained a pH above 5.7 for the shelf-life study, while the control sample decreased to 5.1 after 16 days of storage. Based on pH standards for oyster quality (Cook 1991), results from this study indicated that HHP treatment was able to extend the shelf-life of oysters up to 50%. Moisture results indicated that HHP treated oyster absorbed more water than the controls. HHP reduced initial microbial load and inhibited microbial growth during storage at refrigerated temperatures. After 14 days in storage the HHP samples were 2–4 logs lower in total aerobic counts and anaerobic count. In general, the higher pressures were more effective in lowering microbial counts. Descriptive tests showed that HHP treatment extended the shelf-life of oysters. All pressure treated oysters scored higher in descriptive evaluations than hand shucked oysters over the storage period. These results showed that pressures between 35,000–40,000 psi with a holding time of 1–2 min were effective in (a) shucking oysters, (b) reducing microbial count, and (c) causing minimal changes to the appearance of raw oysters. Although the effect of HHP on oysters may be dependent on species and seasonality, HHP is a promising method for shucking oysters and extending their shelf-life.

CONCLUSIONS

This study showed that HHP treatments were effective in producing safe, high quality oysters. In this study, a pressure treatment of 35k, for 2 minutes was optimum for shucking the oysters. Research will be continued to determine the effects of HHP on *Vibrio parahaemolyticus* inoculated into whole oysters.

PRESSURES ON NEW JERSEY SHELLFISH WATERS

WILLIAM EISELE,* BONNIE J. ZIMMER, AND ROBERT CONNELL

New Jersey Department of Environmental Protection, Bureau of Marine Water Monitoring, PO Box 405, Leeds Point, New Jersey 08220

INTRODUCTION

Since 1978, the State of New Jersey has been able to restore more than 90,000 acres of shellfish waters to harvestable status. These restoration efforts have resulted in classifying approximately 88% of the shellfish waters in the state as harvestable. (Harvestable waters include all shellfish waters from which shellfish are available for either direct market or market after additional purification, such as depuration.) Therefore, the state's goal to classify 90% of the waters as harvestable by 2005 is close to being achieved (Fig. 1). Additional waters have improved to a less restricted harvesting status. Most of the improvement in water quality prior to 1995 was directly related to improvements in domestic waste treatment. Evaluations of shellfish waters may be found at www.state.nj.us/dep/watershedmgt/bmw.

New Jersey is a densely populated state with a highly developed waterfront area. Much of the infrastructure, particularly in the northern coastal areas, has been in place for many years. As a result, existing pressures on water quality in shellfish waters are comprised primarily of non-point sources and unpermitted discharges.

POINT SOURCE PRESSURES

Point sources of domestic waste from treatment facilities have been consolidated into regional treatment facilities. There are no longer any permitted domestic waste point sources located in the back bay areas; all discharges are located in the deeper waters of the Atlantic Ocean. Consequently, the pressure on shellfish waters from these sources has diminished.

Pressures from unpermitted point sources, primarily spills, continue (Fig. 2). Although there are numerous unpermitted discharges into saline waters each year, most are insignificant. However, during the period between 1995 and 1999, nine unpermitted discharges resulted in suspension of harvest. Each resulted from a discharge of raw or partially treated domestic waste. The Bureau of Marine Water Monitoring routinely responds to situations in which sewage or other pollutants have been discharged into saline waters. Most of these discharges are the result of excessive inflow into collection systems during storm events or breaks in lines carrying waste materials. In some cases such discharges result in suspension of shellfish harvest in the affected waters.

NON-POINT SOURCE PRESSURES

Non-point source pressures on shellfish beds in New Jersey originate in materials that enter the water via storm water. These materials include bacteria as well as other waste that enters the storm water collection system.

The Bureau of Marine Water Monitoring has identified areas where the bacteriological water quality is adversely affected by storm water and has begun to identify particular storm water outfalls that discharge excessive bacteriological loads during storm events (Fig. 3). Areas were identified by comparing fecal coliform levels measured after significant rainfall with those measured after a period of dry weather.

In some cases, specific discharge points can be identified, as in the example of Seaside Heights, New Jersey, shown in Figures 4–6. In this case, a small area in Barnegat Bay adjacent to Seaside Heights was identified as a storm water–affected area, as described above. The area was surveyed to determine potential sources, including locating storm water outfalls, marinas, and areas of dense

Figure 6. Seaside Heights, NJ, concentration of *E. coli* 3 h after onset of precipitation.

wildlife populations. Samples were then analyzed during a significant storm event for *Escherichia coli* to further pinpoint the specific sources of bacterial contamination. Two storm water outfalls (of the 18 located in the area), where *E. coli* concentrations were >1,400 cfu/100 ml, were identified as probable sources (Fig. 5). Three hours after onset of precipitation, counts greater that 1,400 CFU/100 ml were measured in the northeast corner of the cove (Fig. 6). During the previous 2 h, strong winds from the southwest and incoming tide (entering under the bridge shown at the bottom of the map) affected the distribution of bacteria in the cove.

When specific outfalls are identified as significant sources, the Department of Environmental Protection works with the county and municipality to further refine the source(s) of the contamination and implement remediation activities. Next steps involve identifying the drainage area of the specific outfalls and then monitoring within the drainage area to identify the actual source(s) of the bacterial contamination. Once these have been identified, the state and local governments work to correct the problem.

CONCLUSIONS

Because it is often difficult to identify specific non-point sources of contamination, remediation of non-point pollution can become costly. This project demonstrates that a well-designed plan for sampling and analysis can help target resources to the specific areas causing elevated bacterial levels. Approximately 10% of the storm water outfalls in the area contribute significantly to the water quality impairment. Additional work is planned to differentiate between human and nonhuman sources (coliphage analyses) as well as to identify actual sources within each affected catchment area.

SCIENCE, FOOD SAFETY REGULATIONS AND EUROPEAN SHELLFISH CULTIVATION

DOUGLAS MCLEOD

Association of Scottish Shellfish Growers, 'Mountview', Ardvasar, Isle of Skye GB-IV45 8RU Scotland, United Kingdom

Across Europe, shellfish farms are generally located in relatively unpolluted waters in peripheral regions, far from the madding crowds and their inevitable discharges to the environment. And across the European Union the shellfish cultivation sector promotes its natural, "organic" products as cultured in an environmentally friendly and sustainable manner. Yet, in recent years not only has the sector felt that it has been subject to excessive hygiene regulations, but consumers have been bombarded with images of a food product that is indistinguishable from the more intensively farmed species such as poultry, cattle, sheep, and salmon. Underlying this dichotomy and giving legitimacy to "food scare" stories is the body of science that identifies valid food safety concerns but fails to adequately define the risk factors involved and in effect contributes to the current climate of food hysteria.

Production of cultivated shellfish in Europe (1997) totalled some 665 thousand tons (KT), a volume dominated by mussels, which, at 515 KT, represented about three quarters of European output and around 70% of global production. Oyster production (*Ostrea edulis* and *Crassostrea gigas*) reached some 100 KT, 15% of total EU cultivated shellfish output but representing only 3% of world volumes. The third group of shellfish assessed, clams, accounted for around 50 KT, some 8% of European shellfish output and 4% of global production. With a first sale value of ~580 million euro (ME), shellfish is worth around 30% of overall European aquaculture. Although still the dominant species, in value terms the importance of mussels declined to 47% of the total, at some 270 ME, whereas first sale values for oysters and clams totalled around 150 ME for each species (26–28%). Average prices ranged from just over 500 E/ton for mussels to 3,000 E/ton for clams.

There is an equally skewed distribution of the location of activity across the Union. Shellfish production is geographically extremely concentrated, with 73% attributable to only three countries—Spain, the leader, with 198 KT or 30% of the total, followed by Italy with 143 KT (22%) and France at 141 KT (21%). In addition to these production and value parameters, a further particularly significant attribute of shellfish farming, reflecting the relatively "low tech" nature of operations, is the contribution it makes to employment opportunities. The sector is calculated to generate around 20,000 full time equivalent jobs in the production segment alone, over 50% of total direct employment in the European aquaculture industry.

Turning to food safety legislation, the initial thrust of EU-based food safety legislation took place during the late 1970s and early 1980s, when almost fifty directives relating to water and food quality and associated issues passed into national legislation. A total cost of $70 billion over the past 15 years for the UK alone has been estimated for the implementation of these directives. The main drivers for these and subsequent directives have been the need for harmonization of regulations in the context of the "single market" and the aim to improve food safety. In addition, there have been a number of high-profile food quality–related concerns—the European list is extensive, including BSE (beef), dioxins (poultry), listeria (milk, cheese), salmonella (eggs), *Escherichia coli* 0157 (meat products), Chernobyl fission products (lamb, mutton), GMOs/transgenics, residues (growth promoters, antibiotics, pesticides, heavy metals, hydrocarbons [PAHs]), etc.

The harmonization of specific shellfish food safety legislation was introduced in 1991, with two related directives, 91/492 and 91/493. The latter covers "fisheries products," whereas the former has the greater relevance for molluscan shellfish farmers because it focuses on "laying down the health conditions for the production and the placing on the market of live bivalve molluscs." The main objective for the directive, including later amendments, is to protect human health through the establishment of common requirements for harvesting, handling, storing, transportation, and distribution of molluscs, including permitted maximum levels of bacteria and biotoxins, classification of harvesting areas, and authorization of depuration centers. The fundamental objectives of 91/492 and the other food standard directives, namely, to improve the quality and safety of food, are applauded by the industry, in principle, because shellfish farmers recognize the paramount importance of minimizing the risk to human health from their products and have always been aware of public concerns over shellfish. They also recognize the positive benefits of harmonized standards across a single market of 250+ million potential consumers and that higher hygiene standards will improve the product image with the public. Indeed, any reduction in reported or alleged shellfish "poisoning" stories in the media is always gratefully welcomed by the industry, which believes its products are too often unfairly blamed for consumers' overindulgence, not necessarily of shellfish! Nevertheless, the industry also has some significant concerns about both the legislation itself and the manner of its implementation, and a number of legitimate queries have been voiced. Other industry criticisms about the details of the legislation include complaints about paper trails that don't work, water recycling criteria without scientific justification, the use of "old fashioned" bacterial indicators for the viral problem, and the continued reliance on the unfortunate "mouse" test.

The cost of compliance with Directive 91/492 has proved to be a major financial burden for the sector due to the extent and detail of the new requirements for harvesting equipment, depuration and dispatch facilities, and transportation units. Necessary capital expenditure alone over the first five years after introduction has been estimated to total some 350 ME, and ongoing incremental operating costs (personnel, equipment, facilities, overhead, documentation, testing, etc.) have been estimated at a minimum 30 ME per year.

In addition to these direct financial costs, there has been the indirect cost of lost output as investments into expanding production capacity were diverted into equipment and handling facilities while profit margins, required to finance future expansion programs, were slashed. Although clearly only an estimate, comparing potential expansion with actual volumes during the mid-1990s (minimal growth for oysters and clams, and a decline followed by slow recovery for mussels), the cumulative value of lost produc-

tion has been calculated at some 500 ME. Furthermore, lost production across the EU as a result of closures for apparent biotoxin contamination (PSP, DSP, ASP) above the Action Levels is estimated at an additional 50 ME for the period since 1992. In aggregate, these are not insubstantial sums, even for an industry with an annual turnover in 1997 of almost 600 ME!

Regular monitoring for biotoxins is a long-established practice in many European countries, as it is elsewhere; however, since the introduction of 91/492, the process has become more extensive and more regular while the techniques and protocols of the analyses have become more standardized, at least in theory. The network of national reference laboratories, combined with a central European Reference Laboratory (located at Vigo, Spain for this topic), enables scientists to tap into an extensive database of information and discuss in an informed manner the various issues of concern as expressed by food safety interests and the production sector.

Reported presence of PSP toxins in European shellfish over the past decade has ranged widely, from the Straits of Gibraltar to the North Cape, with a generalized perception that the incidence is becoming both more intense (higher levels of toxin) and more frequent. But whether this is a long-term trend or part of a cycle has not yet been determined; there are still many who insist on the latter, pointing out that biotoxin contamination is a natural phenomenon and the source of many cultural and religious regulations about shellfish consumption. The detection of DSP toxins has also been a regular and widespread event over the decade, although in comparison with PSP, there appears to this author to be a southern and western "shunt" in incidence. ASP is the "new kid on the block," and so inevitably there are more limited indications of presence, with reports limited essentially to Scotland and Spain (one positive from Denmark and two from Portugal).

With only limited closures for PSP and DSP (although a greater incidence of the latter than in previous years), 1999 was without doubt the "year of ASP," particularly in Scotland. There were extensive closures both there and in Ireland, significantly limited almost exclusively to scallops (*Pecten maximus*), which made it a bit of a Celtic event, although there were reports of ASP in Galicia, Spain. This particular biotoxin event has not been "just another closure," but has had a number of specific characteristics and has raised several novel issues:

- As mentioned earlier, the toxin accumulation was restricted almost exclusively to scallops;
- Both cultivation and capture fishery sectors were affected, compared with the historical situation where closures due to PSP and DSP have largely affected only the farmers, who currently have relatively limited economic and political weight;
- The geographical extent of the "event," extending the length of the western coast, from Cape Wrath to the southern border with Ulster waters, areas off the eastern coast, and the Northern Isles;
- The temporal extent, from May 1999 for some twelve months (albeit, eventually, over a diminishing area);
- The use of FEPA (Food and Environment Protection Act) Orders to close areas, including shellfish farms, in contrast to the more flexible Voluntary Closure Agreements, which had previously been the normal management tool;
- The creation of a climate of uncertainty and distrust, fostered by poor communication between authorities (including scientists) and industry, lack of clarity on the testing methods, a specific suspicion of the negative impact of salmon farming on plankton populations, and perceived lack of government and scientific interest in the plight of the scallop sector and by inference the marine environment.

As the closures continued, there were increasing demands for focused research into the cause of the ASP event (because if this was a fact of life, with endemic reoccurrence, then the industry needed to restructure swiftly).

As the closures spread, there was an ever more vocal call for a review of the management regime, which appeared, in the United Kingdom at least, to have only two settings—"go" and "total stop"! Other countries, most notably our close neighbor, Ireland, appeared to have discovered a middle way, whereby the fishery and farms could continue harvesting despite ASP analyses above the Action Level but only place shucked scallop meats on the market. This approach reflected the reported differential accumulation of toxin in the different parts of the scallop, with the majority to be found in the hepatopancreas and only trace amounts in the adductor muscle (the white meat). Indeed, the Association of Scottish Shellfish Growers carried out a small-scale research project to try to establish this differential accumulation in some of their own animals. The results showed that 100% of "total tissue" results were significantly > Action Level of 20 μg/g (site means ranging from 112 to 203 μg/g for 4 separate locations), whereas the hepatopancreas accumulated in excess of 95% of the toxin (ranging from 1,400 to 2,600 μg/g). However, for the edible body parts, only 25% of "gonad alone" results were > Action Level, while zero "adductor muscle alone" results were > Action Level (83% below 10% of Action Level), and zero "adductor plus gonad" results were > Action Level (75% below 10% of Action Level).

These results indicate that the threat to public health from the consumption of adductor and gonad together, from scallops with relatively high concentrations of ASP as measured by a total tissue analysis, was, in terms of consumer risk, essentially nonexistent. The theoretical public health risk was further reduced if consumption of only adductor muscle is assessed. As a result, the Scottish industry has been demanding a comprehensive review of the current monitoring, testing, and management regime, both in Brussels and in the United Kingdom.

Achieving this objective will require a major contribution from the scientific community. First, there must be a greater effort from scientists to communicate with industry, to explain and justify procedures and priorities; lack of transparency creates a sense of exclusion and distrust, which in turn leads to fear and hostility. Second, scientists must venture down from their apocryphal ivory towers and debate research priorities with industry, seeking to identify R&D that will support and assist industry rather than subject it to additional constraints; after all, without an industry to support, there would be less call for their scientific expertise! Third, scientists must evaluate realistic levels of risk to human health, transferring experimental laboratory results into the context of the real world and transforming them into pragmatic policy parameters.

CONCLUSIONS

In the real world, where people need income-generating activities (jobs), where all foods can never be, and indeed should never be, 100% risk free, where there is a need for a rational risk assessment seeking the optimal way forward for all sections of society, the demand for responsible science is urgent. Protection of consumers from marine biotoxins, without destroying the supply chain, through appropriate scientific research, the application of

reason, and pragmatic, risk assessment–based management systems should be a common objective of science and industry. The intervention of credible and comprehensive science is essential in order to overcome the paranoia of politicians and bureaucrats driven by post-BSE angst.

A real world shellfish hygiene management regime must incorporate both monitoring and risk assessment, with the twin objectives of safeguarding public health while enabling shellfish producers to continue to supply quality products to the marketplace. For example, for biotoxins specifically, such a system would display the following elements:

- *For monitoring purposes*, sampling of the water column for evidence of rising cell counts of potentially toxic phytoplankton and diatoms;
- *For monitoring purposes*, total tissue testing, to establish the presence of biotoxins in shellfish populations;
- *For food safety purposes*, testing of toxin levels in the gonad (highest toxin loading of the edible portions):

If < Action Level, marketing should continue of both the shucked meats (adductor and gonad) as well as whole, in-shell scallops with a health advice note (analogous to the currently required Health Mark) stating "Only the white meat and coral (adductor muscle and roe) of these animals should be consumed";

If > Action Level, sales of whole scallops should be suspended and sales of adductor muscle alone would be permitted from authorized processing facilities.

Such a system would prioritize the concern for safeguarding public health while addressing the "specific risk material" issue and targeting the testing regime on the product being placed on the market. There is a clear role for science in this situation to assist in creating and supporting such multifaceted solutions to problems.

HARMFUL EFFECTS OF THE TWO PILATE MOLLUSCAN SPECIES *CYMATIUM PILEARE* AND *LINATELLA CAUDATA* ON THE CULTURE OF PEARL OYSTERS IN VUNG RO SEA WATER, PHU YEN, VIET NAM

NGUYEN CHINH

Research Institute for Aquaculture No. 3, Nha Trang, Viet Nam

ABSTRACT *Cymatium pileare* and *Linatella caudata* are two injurious predators to the pearl oyster *Pinctada martensii* cultured in Vung Ro cove, Phu Yen Province, Viet Nam. Ten culture cages of *P. martensii* containing 150 individuals each were kept under observation. After nearly a year of observation, the initial number of oysters, 1,500, was decimated by the two predators and reduced to only 67. Today, there are no better methods of destroying *C. pileare* and *L. caudata* than pulling the cages to the surface once every ten days to get rid of the predatory shells.

The pilates *Cymatium pileare* (Linne, 1758) and *Linatella caudata* (Gmelin, 1791) both belong to the family Cymatiidae, the superfamily Cymatiacea, the order Mesogastropoda, and the class Gastropoda. The species *C. pileare* (Linne, 1758) is fairly widely distributed and characterized by certain secondary varying features, assuming such forms as *C. pileare* from *aquatile* (Reeve, 1844) and *C. pileare* from *intermedium* (Pease, 1869). The species *L. caudata* has synonyms of *Linatella cingulata* (Lamarck, 1822) and *Linatella cutacea* (Lamarck, 1816).

The shell of *C. pileare* is big, heavy, lozenge shaped and oval (Fig. 1). *C. pileare* is widely distributed in the coastal waters of the Indian Ocean, Pacific Ocean, and other expanses in the Atlantic Ocean. The distribution is also reported in Vietnam's coastal seawaters. The carnivorous creatures attach themselves to sublittoral gravels at depths of 2–3 m. At an early stage, the shell cortex develops into a pile, making the body light enough to be attached to floating objects. At Vung Ro, *C. pileare* in pearl oyster cages ranged in size from 18–59 mm (height) and 10–31 mm (breadth) (Table 1).

Shells of *L. caudata* are of moderate size, and the body base abnormally bulges outward (Fig. 2). Like *C. pileare*, *L. caudata* is widely distributed from the coastal waters of the Pacific Ocean, the Indian Ocean to the Atlantic Ocean, and South Africa. The distribution is also reported in Vietnam's coastal seawaters. Its distribution according to water depths and substrata is similar to that of *C. pileare*. At an early stage, the shell cortex develops into a pile, enabling the creature to attach itself to floating objects. The species is carnivorous. Table 2 shows the ranges in size for *L. caudata* in pearl oyster cages at Vung Ro.

TABLE 1.

***Cymatium pileare* sizes in pearl oyster *P. martensii* culture cages at Vung Ro on April 21, 2000.**

Order	Height (mm)	Breadth (mm)	Height-to-Breadth Proportion
1	18	10	1.80
2	39	21	1.85
3	40.5	20.5	1.97
4	42.5	24	1.77
5	44.5	26	1.71
6	52	29.5	1.76
7	57	29	1.96
8	58	32	1.78
9	59	31	1.90

We observed that the floating larvae reaching the spat stage attached themselves to the shells of the growing oysters. The radulae and mandibles gradually took shape. The creatures, attached to the viscera of the oysters, gnawed away the oysters' flesh with their radulae and mandibles, causing the oysters' death. As a result, the number of oyster decreased in cages with increasing numbers of snails.

Ten rectangular pernio-netting cages were used to determine harmful effects of *C. pileare* and *L. caudata* on cultured pearl oysters. Each cage contained 150 seed oysters ranging in size from 2–3 cm. Inspections were conducted twice each month and involved destroying the snails in the cages and counting the dead

Figure 1. ***Cymatium pileare*** **shells.**

10	46	29	1.58
11	48	29	1.65
12	61	37	1.64

oysters. Temperature and salinity were kept under strict observation during inspections.

After nearly a year of study, it was observed that the initial 150 pearl oysters cultured in each of 10 cages was reduced to only 38 in cage No 5 and 29 in cage No 6. The total number of remaining live oysters was 67, 1,433 having died. If 30% of the oysters (430 oysters) died from natural conditions and weakened resistance, then those oysters which were destroyed for food by *C. pileare* and *L. caudata* would number 1,003 (Table 3). *C. pileare* and *L. caudata* are therefore a great danger to the culture of the pearl oyster *P. martenssi*.

Observing oysters for the appearance of shells of the two pilates over a period from January to November 1999, we found that the two species appeared in the same seasons. In the pearl oyster cages, *C. pileare* accounted for 55–60% and *L. caudata* accounted for 40–45%, with more shells in cages at a water depth of 5 m than in those at 2 m. In March, young shells appeared in large numbers and grew quickly. They also appeared in June. This suggests that *C. pileare* and *L. caudata* reproduce from February to March and from May to June. From July on, no offspring were seen. If cages are checked every half month to remove existing pilate shells, only 1 or 2 shells can be found in the cage the next check time, but if shell-removing times are 30–45 days apart, 3 and sometime 7–8 shells are found in cages.

Currently, there is no better method for getting rid of *C. pileare* and *L. caudata* than pulling cages out of the water and destroying the shells every 10 days. Alternative strategies like chemicals or modified salinity would negatively affect the growth of *P. martensii* in the cages.

TABLE 3.

The effect of *C. pileare* and *L. caudata* on *P. martensii* survival in cages. Oysters were introduced into cages on December 15, 1998.

EFFECT OF CHLORINE ON DIFFERENT BACTERIAL GROUPS AND EFFECTIVENESS OF THE PURIFICATION OF SEWAGE IN HARVESTED AREAS

B. FERRO-SOTO

Centro de Control da Calidade do Medio Mariño (CCCMM), Peirao de Vilaxoán s/n, Vilagarcía de Arousa-36611 (Pontevedra), Spain

ABSTRACT Besides microbiological monitoring programs, it is important in shellfish harvesting areas to understand the process of purification of sewage discharged in harvesting areas. The objective of this study was to evaluate the importance of purification, the effectiveness of chlorination, and the influence in these areas. Chlorine produced significant reductions on all studied bacterial groups and reductions were among one and two orders of magnitude, being lower for fecal streptococci and aerobic bacteria at 25°C. High quantitative variability was observed with regard to the number of bacteria presents in these waters (W1, W2, W3) but qualitative variability is unknown. Correlation among shellfish samples and W3 (effluent discharged in harvesting areas) was not observed.

KEY WORDS: chlorine, purification, microorganisms, shellfish, microbiological classification

INTRODUCTION

Escherichia coli is the most commonly used indicator of fecal pollution and its presence in the environment is related to the presence of enteric disease (Rice et al. 1991). The EU Directive 91/492/ECC (Anon. 1991) classifies harvesting areas for bivalve molluses into categories A, B, C, and D depending on the level of fecal coliforms and *E. coli*. Harvesting areas from Galicia are divided into categories A, B, and C because along the 1195 km of Galician coast there are no areas where fecal coliform concentrations approach zone D values. A review of the microbiological classification is conducted once per year. The spatial and temporal frequency of sampling is higher than the European, Spanish, and regional regulation (Anon. 1991, Anon. 1993, Anon. 1999) requirements because Galicia is an important aquaculture region where 89% of the total aquaculture in Spain is located (Cruz Ferreiro & Noguera Mendez 1999).

MATERIALS AND METHODS

Between July 1998 and April 2000 three samples of water were analyzed every 15 days from a sewage farm located in Tragove (Cambados-Pontevedra, NW Spain) that concentrates 30,000 habitants. Water sampling sites were established as follow: Water 1 (W1) was untreated sewage; Water 2 (W2) was sewage after biological treatment and before chlorination; Water 3 (W3) was sewage after chlorination. These samples were collected between 9:00 AM and 11:30 AM, waiting approximately 40 min between collection for W2 and W3 to allow chlorine to act on bacteria. The volume of free chlorine was constant (0.1–0.2 mg L^{-1}). In the same period of time, wild mussel sampling occurred every 15 days at three sampling sites (San Sadurniño, Tragove, and Peña Mourelló). From July 1998 to July 1999, a sampling of mussels on rafts took place every 15 days at two locations (Cambados D and Grove A) (Fig. 1). Therefore, data are paired as follows: W2 and W3, to compare the effectiveness of chlorination; W3 and all samples from mussels, to determinate the influence on harvesting areas. W1 data allow the estimation of the concentration of different bacterial groups that arrive at this sewage farm, but this is not discussed in this paper.

Water samples were analyzed by membrane filtration (MF) technique (APHA 1995), except for five months due to equipment breakdown. During that time the multiple tube fermentation technique (APHA 1995) was used for total coliforms, fecal coliforms, and fecal streptococci and the 3M Petrifilm™ (Europe Laboratoires Santé, Cergy Pontoise, France) technique was used for aerobic bacteria cultured at 25°C and 37°C. When using MF, nutrient agar was used for aerobic bacteria at 25°C and 37°C, endo-B agar for total coliforms, m-FC agar for fecal coliforms, Slanetz & Bartley agar for fecal streptococci and TCBS (Thiosulfate Citrate Bile Sucrose) agar for *Vibrio sp.* Incubation times were three days for aerobic bacteria at 25°C, 48 h for aerobic bacteria at 37°C and fecal streptococci, and 24 h for fecal coliforms, total coliforms and *Vibrio sp.* When using multiple tube fermentation, a five tube and three dilution most probable number (MPN) was used. Brilliant green bile broth (BGBB) was inoculated with dilutions made from samples of water (W1, W2, W3), then incubated at 37°C for up to 48 h for total coliforms. Tubes showing gas and/or acid were examined for the presence of fecal coliforms (presence of gas) by subculture to BGBB, prior to incubation at 44.5°C for 24 h. This method was used for fecal streptococci but the medium was dextrose-azide broth (37°C, 48 h). Tubes showing sediment and/or turbidity were subcultured to ethyl violet azide (EVA), incubated at 37°C for 48 h, then examined for the presence of violet sediment (Plusquellec et al. 1983). Aerobic bacteria analyzed by 3M Petrifilm™ were incubated for three days at 25°C and two days at 37°C. One milliliter of the sample was inoculated in a thin special plate and the plate was incubated. The MPN technique was also used for enumerating bacteria in shellfish samples.

All counts are expressed as units for MF and MPN counts and were logarithmically transformed to normalize the variables for statistical analysis. Therefore, data for MF and MPN analyses were combined. Results were analyzed by variance analysis (ANOVA; $P = 0.05$) to determine if the chlorine significantly reduced the levels of the different microorganisms. However, these counts cannot be considered as absolute values because sometimes excess or the absence of growth made counting colonies impossible. To transform results as "higher than" or "not detected" in results suitable for statistical analysis, the following assumption was used: when the result was "higher than" the counting was obtained with the multiplication of the dilution factor by 500 (i.e., for a dilution factor of 10^{-3} this means 10^{-3} by 500), and when the result was "not detected" the counting was obtained with the multiplication of the dilution factor by 1 (i.e., for a dilution factor of 10^{-3} this means 10^{-3} by 1).

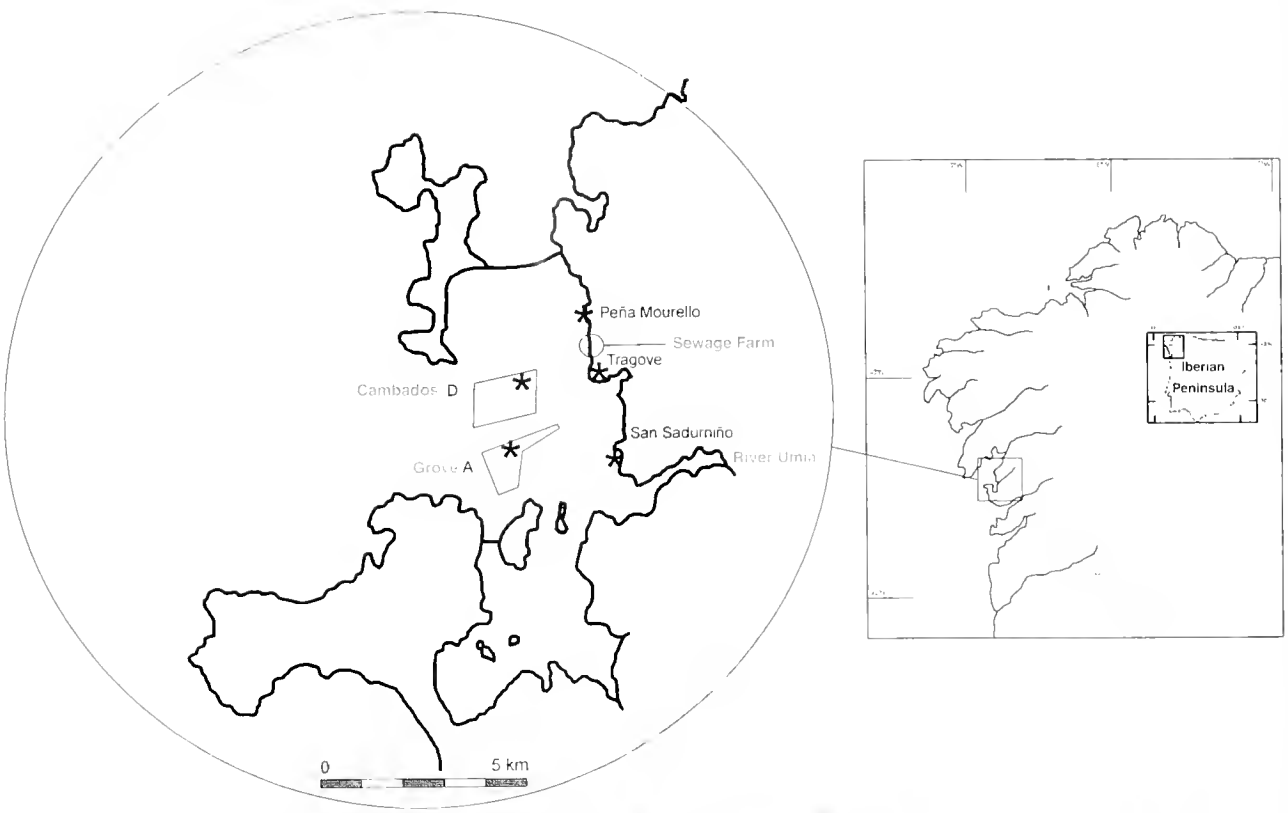

Figure 1. Sampling sites for bivalve molluscs. Cambados D, Grove A: sampling sites of mussel on rafts; Peña Mourelló, Tragove, San Sadurniño: sampling sites of wild mussel (bottom).

TABLE 1.

Average counts (per 100 mL) obtained for the three different types of sewage (W1, W2, W3).

Samples	Aerobic 25 C	Aerobic 37 C	Total Coliforms	Fecal Coliforms	Fecal Streptococci	Vibrio sp
W1	$550 \cdot 10^6$	$360 \cdot 10^6$	58,400,000	3,950,000	1,400,000	1,250,000
W2	39,700,000	10,500,000	2,900,000	680,000	93,000	90,000
W3	2,300,000	650,000	28,000	2,000	1,000	800

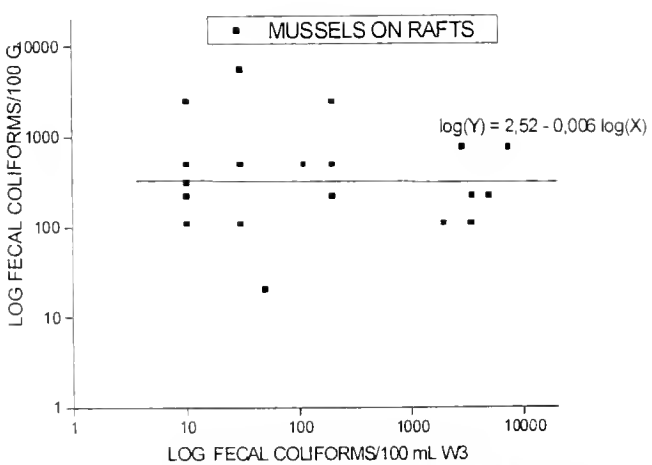

Figure 2. Correlation of log FC concentrations in mussels on rafts and W3 (R = 0.013).

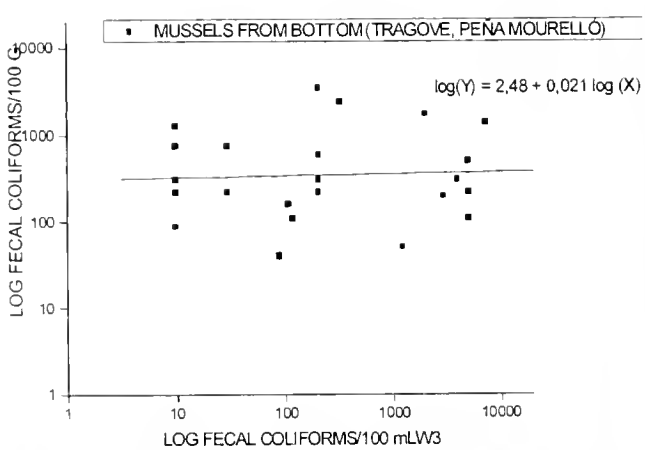

Figure 3. Correlation of log FC concentrations in two sampling sites mussel from bottom (Tragove, Peña Mourelló) and W3 (R = 0.045).

TABLE 2.

Standard deviation (per 100 mL) obtained for three different types of sewage (W1, W2, W3).

Samples	Aerobic 25 C	Aerobic 37 C	Total Coliforms	Fecal Coliforms	Fecal Streptococci	Vibrio sp
W1	$630 \cdot 10^6$	411,000,000	97,450,000	4,500,000	2,280,000	2,100,000
W2	$94 \cdot 10^6$	14,000,000	4,100,000	2,950,000	140,000	160,000
W3	9,350,000	2,200,000	52,000	2,200	1,980	1,800

RESULTS

Averages (Table 1) and standard deviations (Table 2) show values not logarithmically transformed. High variability was observed with regard to the number of microorganisms present in these waters. This variability could be explained by the fact that at the sewage farm in Tragove, bacteria enter by routes other than as feces; for example, bacteria enter the farm in rainwater and effluent from factories related to seafood and therefore environmental microorganisms can be detected in W1, W2 and W3.

Chlorine produced a significant reduction (ANOVA: $P = 0.05$) for all groups of microorganisms in effluent from the sewage farm (W3). These reductions were two orders of magnitude for bacteria at 37°C, total coliforms, fecal coliforms, *Vibrio sp.* (colonies grown on TCBS) and one order of magnitude for aerobic bacteria at 25°C and fecal streptococci. Lower reductions for fecal streptococci (Ritter & Treece 1948) may be explained by the fact that these bacteria adhere to each other in chains and clusters of various size and appear to be more resistant to disinfectants (Berg 1978). With regard to aerobic bacteria at 25°C, they comprise a heterogeneous group wherein the resistance to disinfectants is very different (Haas & Engelbretch 1980). For all waters (W1, W2, W3) a decrease in the number of bacteria was observed when aerobic bacteria at 37°C, total coliforms, fecal coliforms, fecal streptococci and colonies grown on TCBS were considered sequentially (Table 1). Lower counts of total coliforms than aerobic bacteria (37°C) are expected because mesophilic microorganisms comprise a much larger number of organisms than that constituted by total coliforms, which are defined as those that catabolize lactose with the formation of acid and gas (APHA 1995) at 37°C. Fecal coliforms are as subgroup of total coliforms. The higher number of fecal coliforms than fecal streptococci is explained because fecal coliforms, generally, are more abundant in human feces (Peres et al. 1980).

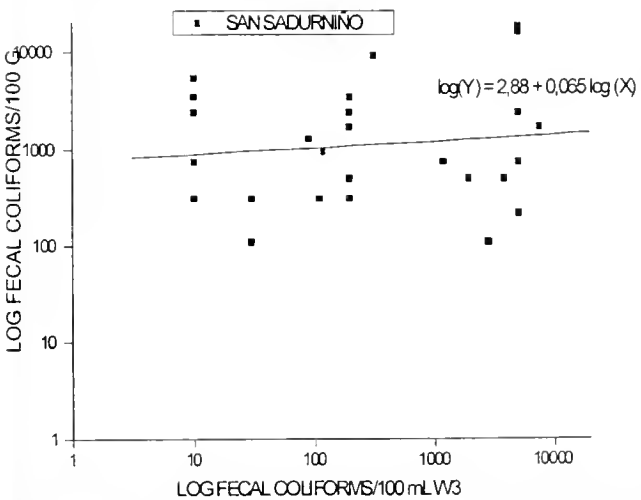

Figure 4. Correlation of log FC concentrations in one sampling site mussel from bottom (San Sadurniño) and W3 (R = 0.018).

Some species were isolated from colonies on the various agar media, most of them *E. coli* (eosine methylene blue agar Levine), *Klebsiella pneumoniae* (eosine methylene blue agar Levine), *Aeromonas hydrophila* (TCBS agar) and *Vibrio alginolyticus* (TCBS agar), but other isolates were not possible to identify. The number of sucrose-positive colonies was higher than the number of sucrose-negative colonies on TCBS. Counts of bacteria on TCBS were referred to as "microorganisms grown on TCBS" because it was not possible to identify some of them (all were oxidase-positive). Bacterial groups were identified using API 20E and API STREPT (Biomerieux, Maercy l'Etoile, France).

DISCUSSION

shellfish were used to establish a comparison with fecal coliforms in W3, even though in Galicia harvesting area microbiological classification is based on *E. coli*. In all sampling sites, except San Sadurniño, no significant differences (ANOVA: $P = 0.05$) have been observed for fecal coliform concentrations in shellfish and fecal coliform concentrations in W3. Correlation for this parameter in sampling sites and W3 was not observed (Fig. 2: R = 0.013; Fig. 3: R = 0.045; Fig. 4: R = 0.118), but it is possible that the high flow of the effluent (6000 $m^3 L^{-1}$) contributes to the presence of fecal coliforms in the area. Obviously, the dynamic nature of marine waters (Rosón et al. 1996, Peres et al. 1980) probably would have a significant influence. The different behavior for San Sadurniño may be related to its proximity to the mouth of the River Umia (Fig. 1) and therefore other conditions could have an effect (i.e., fecal coliforms from villages near the river that are carried out by it).

THE USE OF NONGOVERNMENT SAMPLERS IN DELIVERING A GOVERNMENT-MANDATED SHELLFISH SANITATION PROGRAM

NIGEL HARRISON
Office of Sustainable Aquaculture Fisheries and Oceans, 200 Kent Street, Ottawa, Ontario, K1A 0E6, Canada

INTRODUCTION

In the past, the shellfish sanitation programs in many areas of North America were adequately funded compared to the needs of the industry. To some extent, this was due to the localized nature of the industry, with government offices located nearby. In addition, the abundance of other fisheries caused in some locations shellfisheries to be relegated to seasonal work or employment by limited populations.

Today, after decades of downsizing or rightsizing, we are seeing a decrease in the ability of the government to provide basic services in all areas and to provide specialized services in some areas. Ken Georgetti (2000) writes, "When what are essentially public services are delivered by private industry, the onus is on industry to prove the safety of its products or services. Regulation requires stringent scientific testing to prove safety, lengthening the time it takes to get a product or service to market. Once there, it requires rigorous adherence to safety standards. This onus to ensure safety costs business money. Deregulation is about increasing the margin of profit by cutting the cost of doing business."

Compounding this is the increase in both public awareness in safe food and the use of the resource due to the decrease in stocks of other fisheries. The worldwide boom in aquaculture has allowed employment in rural areas at a time when services to rural centers have been curtailed. In addition, the recognition of the rights of other users, such as aboriginal and the public, has seen the shift in direction for the program away from a traditional wild harvest. These fisheries have in some cases seen shellfish consumed in the raw or lightly cooked state according to the influence of ethnic and traditional backgrounds. This increased demand has led to regional "band-aid" solutions. These ad hoc arrangements, while solving immediate needs, have led to the increased liability to a government due to the lack of a system of checks and balances.

CASE STUDIES

To address these concerns, a government must be proactive. In February 1992, the Fish Inspection Directorate of Fisheries and Oceans (DFO; now the Fish, Seafood and Production Division [FSPD] of the Canadian Food Inspection Agency) introduced a new and innovative approach to fish inspection called the Quality Management Program (QMP). The program was developed jointly through the cooperative efforts of the fish processing industry and DFO and is based on five of seven HACCP (hazard analysis and critical control point) principles. It has since been reengineered to include all the requirements of an HACCP program.

The acceptance of greater responsibility by industry in monitoring and controlling their processes in compliance with the regulations has permitted FSPD to assume an auditing role and focus on areas where there is higher risk. The resulting efficiencies in the systems have allowed FSPD to continue to deliver a comprehensive inspection program that provides even greater assurances that Canadian fish products meet international market requirements. In many cases, QMP allowed industry to take on monitoring and controlling critical health risks that were once the responsibility of government. This was only possible because the QMP provided a structure for nongovernment inspectors to assess health and safety concerns that could be audited by regulators.

Another example is monitoring, control, and surveillance. Monitoring, control, and surveillance (MCS) refers to the systems and processes used to gather complete and accurate information about a fishery and ensuring that a fishery is conducted in accordance with a fisheries management plan and fisheries regulations to control the fishing practices of industry. Dockside monitoring is the process used in most fisheries, except the lobster fishery, to gather information about landings by individual fishers. Fishers procure the services of a dockside monitoring organization to monitor their landings of fish and report them to the Department. The Auditor General of Canada found several instances of deficiencies with the program when it audited in 1997 (Canada, 1997):

- The Department had not quantified the potential error resulting from misidentification of the species and weigh of incoming fish;
- The dockside monitoring program is not always carried out by organizations that are at arm's length with the harvesting sectors in the region;
- The dockside observers would not be able to ensure that all fish landed would be included in the Department's catch data systems.

LIABILITIES

Recently, in the province of Ontario, Canada, water contaminated by *Escherichia coli* O157 caused 2,000 illnesses in the small town of Walkerton. The majority of reported cases occurred after 12 May 2000 and continued until late June 2000. Of the 1,346 reported cases identified, 1,304 were considered to be primary or caused by direct exposure to Walkerton municipal water. The estimated overall number of cases associated with the outbreak exceeded 2,000. Sixty-five patients were admitted to a hospital, and of these, 27 developed hemolytic uremic syndrome. Six people died as a result of the outbreak (Canada, 2000).

A series of unfortunate circumstances occurred to cause an outbreak of this magnitude. These included heavy rains accompanied by flooding, *E. coli* O157:H7 and *Campylobacter spp.* present in the environment, a well subject to surface water contamination, and a water treatment system that may have been overwhelmed by increased turbidity. Bacterial monitoring can only identify a contaminated source after the contamination has spread through the water system and put the public at risk. However, compounding these issues were policy decisions made by the Ontario government.

In 1996, Eva Ligeti, the environment commissioner at the time, admonished the government for compromising environmental protection, pointing specifically at the testing of drinking water. For

years, the Ministry of Environment and Energy and the Ministry of Health provided drinking water testing to municipalities. With little notice, these services were transferred to municipalities that had to find testing labs and the money to pay for them. The public was not consulted, nor were municipalities (National Post, 2000). The Ontario Ministry of the Environment operating budget was cut 42.4 per cent from $287 million in 1994/1995 to $165 million for 2000/2001.

CONCLUSIONS AND RECOMMENDATIONS

To address these liabilities, a sampling program must be carefully designed, implemented, audited, and documented. Some of the parameters of the program that must be considered are the activities (patrol, water or biotoxin sampling), responsibilities of various personnel, the control of records, the standard operating procedures for sampling, the control and calibration of sampling equipment, and the conditions for shipping to laboratories. Additional control must be implemented if private laboratories are being utilized. Finally, a plan must be in place for the control of nonconformities in sampling.

Government must directly audit these programs. They must seek their own data to compare with that collected by the nongovernment authority. Within the relationship with these samplers there must be a direct authority to control their activities. This audit and control program must be documented so as to allow audits by other government departments or foreign governments. An important component of the audit is the assessment of the efficiency and efficacy of the program.

The nongovernment authorities that carry out these activities and the observers whom they employ must be independent of the fishers they monitor. The effectiveness of their program must be audited by the nongovernment controlling authority, and corrections and amendments to the program must be made. The human resource requirements of the sampling programs must be adequately addressed by the needs of personnel, resources, and training of these people. Training must be conducted according to a standardized curriculum developed by the government body. In some cases, this can be problematic because training of government employees has, in some areas, ranged from formal classroom to new staff being presented with keys and a copy of the regulations. If carefully planned and implemented, a program utilizing nongovernment samplers can be a useful addition to a government's shellfish sanitation program.

DEPURATION OF *ESCHERICHIA COLI* FROM SYDNEY ROCK OYSTERS AFTER HARVESTING AND STORAGE. **Iona Reid, Paul Heiskanen, Graham H. Fleet,** and **Ken A. Buckle,** Department of Food Science and Technology, The University of New South Wales, Sydney, NSW 2052, Australia

In New South Wales, Australia, it is mandatory to depurate oysters for 36 h at ambient temperatures (14–25°C) prior to sale. As a consequence of commercial and marketing demands, it is common practice for farmers to harvest and store oysters out of water for periods up to 7 days prior to depuration. It is not known if this practice affects the efficiency of depuration with respect to elimination of microbiological pathogens. In Australia, oyster safety is measured using the indicator organism *Escherichia coli*, where the legislative limit at which oysters can be sold after depuration is 2.3 *E. coli*/g of oyster flesh.

To determine if storage affects depuration efficiency, experiments were designed in which freshly harvested Sydney Rock oysters were artificially contaminated with *E. coli* to levels of 10^2–10^3, stored for 0, 4, 7, and 10 days at 15°C and 23°C, and then tested for their ability to eliminate *E. coli* during depuration. Depuration conditions (salinity 35 ppt, water temperature 14°C and 23°C) were chosen to reflect the estuary conditions from where the oysters were harvested. Each storage experiment was conducted in triplicate. During depuration, samples consisting of 10 oysters each were removed at 0, 6, 12, 24, 36, and 48 h. Oysters were analyzed for *E. coli* using the direct plating method of Anderson and Baird-Parker. Samples were plated onto Tryptone Bile Agar plates overlaid with nitrocellulose membranes and tested using indole reagent as detailed in the Australian Standard (AS 1766).

During storage of contaminated oysters at both 15°C and 23°C, it was noted that *E. coli* levels within the oyster prior to depuration decreased by 95% from day 0 to day 10. This has important implications for the reliability of using *E. coli* as an indictor of safety in oysters.

Oysters stored for up to 10 days met the legislative standard of 2.3 *E. coli*/g after depuration for 36 h. However, stored oysters exhibited some mortality during depuration. After 7 days of storage, mortality rates during depuration and after storage at 15°C and 23°C were less than 10%. After 10 days storage at 15°C, 24% mortality was observed during depuration, whereas at 23°C only 3% mortality was observed. The death and loss of oysters has economic implications to the farmer. The Code of Practice for Depuration of Oysters in New South Wales (Anon, 1999) specifies that Sydney Rock oysters must not be stored for more than 4 days prior to use in depuration. Our data suggest that it may be possible to extend this requirement to 7 days, thereby providing oyster farmers with more flexibility in their production and marketing schedule, without compromising safety as measured by the *E. coli* standard.

EFFECT OF SALINITY AND TEMPERATURE ON DEPURATION EFFICIENCY OF THE SYDNEY ROCK OYSTER (*SACCOSTREA COMMERCIALIS*). **Paul Heiskanen, Iona Reid, Graham H. Fleet,** and **Ken A. Buckle,** Department of Food Science and Technology, The University of New South Wales, Sydney, NSW 2052, Australia

Sydney Rock oysters (*Saccostrea commercialis*) are cultivated in estuaries along the New South Wales coastline, which extends over a distance of 1,400 km from north to south of the state. Depuration is mandatory for all oysters offered for sale in New South Wales and is governed by a Code of Practice for Depuration of Oysters in New South Wales (Anon, 1999), which prescribes parameters such as water temperature (between 14°C and 25°C) and salinity (greater than 18 ppt). After depuration, oysters must conform to the bacteriological standard, namely less than 2.3 *Escherichia coli*/g. Water temperatures in harvest areas may range from 10–28°C, and salinities from fresh (0 ppt) to 35 ppt, depending on geographical location, season, and climatic conditions. Hence the permitted depuration conditions place a commercial constraint on farmers because there may be a requirement to heat or cool the water or increase water salinity, depending on the location and the season. Commercial farmers consider that oysters adapted to their growing conditions should depurate effectively at these conditions to reach the required level of less than 2.3 *E. coli*/g in 36 h, as stipulated in the regulations. Consequently, they believe it should not be necessary to adjust and monitor depuration water to meet the temperature and salinity limits of the Code of Practice.

Experiments were designed to examine the efficacy of depuration of Sydney Rock oysters under extremes of salinity and temperature for particular estuaries. Oysters were artificially contaminated with *E. coli* to 10^2–10^3 cfu/g under conditions that simulated growing conditions, as it was not always possible to obtain naturally contaminated oysters. The oysters were then depurated for 48 h in pilot scale plants in the laboratory under controlled salinity and temperature. Depuration efficiency was measured by the elimination of *E. coli* from oysters using the method of Anderson and Baird-Parker. Samples taken after 0, 6, 12, 24, 36, and 48 h were plated onto Tryptone Bile Agar overlaid with nitrocellulose membranes and tested for indole production to indicate *E. coli* as described in the Australian Standard (AS 1766).

To date, oysters cultivated from two geographical locations have been examined. The first estuary (Hawkesbury River, Central Coast, north of Sydney) experiences temperature and salinity ranges of 14–25°C and 15–35 ppt, respectively. Experiments were carried out on all combinations of 14°, 19°, and 25°C and 15, 25, and 35 ppt, giving a total of nine sets of depuration conditions. Depuration was successful at all combinations of temperature and salinity except for those at 15 ppt, where spawning was induced. The combination of low salinity and higher temperatures also accelerated the onset of spawning. The second estuary (Pambula Lake, south of Sydney) experiences temperature ranges of 10–

22 C with relatively stable salinity (32–35 ppt). Experiments were carried out at 35 ppt salinity and water temperatures of 10°, 12°, 14°, 16°, 18°, and 20°C, with these parameters closely matching growing conditions at the time. Depuration was consistently effective at 14°, 16°, 18°, and 20 C, but at 10° and 12°C some oysters failed to meet the *E. coli* standard.

Further work on estuaries at other locations is currently underway. At the completion of the study, alterations to the Code of Practice will be recommended to accommodate acclimatization of oysters to a wider range of temperatures and salinities, thereby balancing the practicality and economics of commercial processing without compromising end product safety.

NONSELECTIVE ACCUMULATION OF PSP TOXINS IN MUSSELS *MYTILUS GALLOPROVINCIALIS* FED WITH TOXIC DINOFLAGELLATE *ALEXANDRIUM TAMARENSE*. **Toshiyuki Suzuki, Kazuhiko Ichimi,** and **Makoto Yamasaki,** Tohoku National Fisheries Research Institute, 3-27-5 Shinhama, Shiogama, Miyagi 985-0001, Japan. E-mail: tsuzuki@affrc.go.jp

Comparison of paralytic shellfish poisoning (PSP) toxin profiles between natural mussels *Mytilus galloprovincialis* and toxic dinoflagellate *Alexandrium tamarense* collected at the same monitoring site of Ishinomaki Bay, Japan, was carried out by high-performance liquid chromatography (HPLC). The prominent toxins in the mussels and *A. tamarense* were *N*-sulfocarbamoyl toxins (C1 and C2) and carbamate toxins (GTX1 and GTX4). The proportion of carbamate toxins (GTX2 and GTX3) in the mussels was significantly higher than that of *Alexandrium tamarense*.

Mussels *M. galloprovincialis* were reared with the toxic dinoflagellate *A. tamarense*. Changes in both PSP toxin contents and the toxin profiles of mussels during the feeding experiment were monitored by HPLC, and the toxin profiles of mussels were compared with that of *A. tamarense* fed by the mussels. The prominent toxins in the mussels and *A. tamarense* were *N*-sulfocarbamoyl toxins (C1 and C2) and carbamate toxins (GTX1 and GTX4). The toxin profiles of both mussels and *A. tamarense* were almost constant during the feeding experiment. In contrast to the result obtained in the field experiment, remarkable differences in the toxin proportion between mussels and *A. tamarense* were not observed.

These results indicate that the increase of the proportion of carbamate toxins (GTX2 and GTX3) in mussels took place after the accumulation of toxins and denies the selective accumulation of toxins in mussels.

IDENTIFICATION OF *E. COLI* SOURCES FOR THE PECONIC ESTUARY WATERSHED FOR EFFECTIVE MITIGATION OF NONPOINT SOURCE POLLUTION. **Emerson Hasbrouck,[1] Lori Racaniello,[1] George Simmons,[2]** and **Sue Herbein,[2]** [1]Cornell Cooperative Extension Marine Program, 3059 Sound Avenue, Riverhead, New York 11901; and [2]Virginia Polytechnic Institute and State University, 2119 Derring Hall, Blacksburg, Virginia 24061

Studies such as the N.U.R.P. Study and the L.I. 208 Study have identified nonpoint source pollution as a major factor affecting water quality on Long Island. The BTCAMP Study and the Peconic Estuary Program Action Plan identify nonpoint source pollution as a significant contributor to surface water quality problems in the Peconic Estuary.

One of the major components of stormwater runoff is coliform bacteria. Coliforms are an indicator of the possible presence of pathogenic organisms and are used by various agencies to determine water quality. Often the most puzzling aspect of nonpoint source mitigation is determining the exact source of pollutants and hence the best means of remediation. Failing septic systems and wildlife are often credited as major contributors of bacteria to stormwater runoff. However, they require different remediation strategies. In fact, different animal groups also require different remediation strategies.

As a means to identify coliform sources, a DNA library, specific to Eastern Long Island, is being developed based on *Escherichia coli* isolated from the scat of animals (including humans) that live in association with estuaries of Long Island. The DNA library consists of "genetic fingerprints" from pulsed field gel electrophoresis for each *E. coli* isolate. The next step in the process is to take water samples from impacted areas, isolate out pure strains of *E. coli*, and then compare their genetic profile to the known sources in the DNA library. Matches with known sources will identify the animals or animal groups contributing coliform bacteria to the selected water body.

This project will expand the identification process and will additionally contribute to expanding the DNA library. Once the input source or sources have been identified, appropriately tailored remediation strategies can then be developed. Results will provide the ability to identify the animal sources of *E. coli* in nonpoint source pollution and in impacted embayments to develop unique and innovative tools to assist managers in developing and implementing the most appropriate and cost-effective management approaches to stormwater discharge and other nonpoint source pollution remediation efforts.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans,* or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual,* distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").
- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots:* 1000 dpi; *halftones/grayscales:* 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations,* available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Page Charges: Authors or their institutions will be charged $100.00 per printed page. All page charges are subject to change without notice. A handling fee of $50 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints of published papers are available at cost to the authors. Information regarding ordering reprints will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research.* Black and white photographs and color illustrations will be considered.

Corresponding: An original and two copies of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1084 Shennecossett Rd., Groton, CT 06340. E-mail: sshumway@uconnvm.uconn.edu

Membership information may be obtained from the Editor or the Treasurer using the form in the *Journal.* Institutional subscribers should send requests to: *Journal of Shellfish Research,* P.O. Box 465, Hanover, PA 17331.
